Infectious Diseases of the Dog and Cat, 3rd Edition

39.5.2.3

Host Resistance

The ability to experimentally infect animals with *Salmonella* and establish clinical illness depends on many factors. Age is an important variable. Puppies and kittens younger than 1 year are more susceptible to infection and clinical illness than adult animals. Neonates may acquire infections from contaminated secretions of their dams. In utero transmission may result in death and abortion of the fetuses or birth of weak or ill puppies and kittens.

Nutritional considerations are also important in the establishment of salmonellosis. Obesity and overfeeding decreased the resistance to salmonellosis of experimentally infected dogs. Dietary deficiencies of methionine or choline in pregnant animals increase the susceptibility of their offspring to salmonellosis.^{320a}

Stress caused by hospitalization, anesthesia, surgical and medical therapy, and overcrowding has been correlated with an increased risk of salmonellosis in dogs and cats. Thiamylal anesthesia enhanced the virulence of *Salmonella* endotoxin for experimentally infected animals.

The impairment of host immune defenses that occurs with malnutrition, malignancy, and glucocorticoid therapy may increase the prevalence of clinically severe salmonellosis. Immunosuppression associated with diabetes mellitus and feline leukemia virus infection may have contributed to the development of

356

salmonellosis in two cats.⁸⁴ Intranasal modified live virus feline panleukopenia virus vaccination was suspected to cause immunosuppression and an outbreak of salmonellosis in kittens.¹¹⁸ An increased postoperative prevalence of clinical salmonellosis in dogs given high-dose glucocorticoid therapy for intervertebral disc and intraocular surgery has been noted. Salmonellosis has also been reported as a complication of anticancer chemotherapy in dogs and one cat with multicentric lymphosarcomas²⁰⁴ and in a dog with cyclic hematopoiesis.³⁰⁷ The severity of salmonellosis is increased in people with chronic or severe hemolytic anemia, when the mononuclear-phagocyte system is overwhelmed by erythrophagocytosis.

357

The intestinal tract normally is protected against colonization by enteric pathogens, which explains why the clinical prevalence of gastroenteritis is lower than the frequency of *Salmonella* isolation from the pet population. Normal intestinal motility propels ingested *Salmonella* to the cecum and colon. There the resident bacterial population produces volatile fatty acids, including acetic and butyric acids, which limit further replication of the pathogens. Thus any factor that suppresses the animal's indigenous microbial population increases its susceptibility to infection by *Salmonella*. Dogs fed probiotic diets containing large numbers of *E. faecium* had a minor reduction in concentration of *Salmonella* and *Campylobacter* organisms in their stools but a significant reduction in *Clostridia* organisms.⁴⁶² Intestinal mucus itself is not bactericidal; however, it contains humoral and cellular immune factors that are important in protection against salmonellosis.

Antibiotic therapy reduces resistance to salmonellosis and prolongs the course of the illness in experimental animals. A single dose of penicillin or streptomycin greatly increases the susceptibility of mice to salmonellosis by altering the normal intestinal microflora that protects the bowel against colonization by enteric pathogens. In hospitals where outbreaks of salmonellosis had occurred, dogs receiving antimicrobials that alter GI flora, such as ampicillin, were at greater risk of developing salmonellosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

39.5.3 Pathogenesis

Experimentally, numerous organisms¹⁰⁶⁻¹⁰⁹ must be ingested to produce GI colonization by *Salmonella* with or without clinical illness. Because a large proportion of ingested organisms are destroyed by the low pH of the stomach, reducing the amount of gastric acidity by administration of buffered compounds or performing vagotomy or partial gastrectomy induces a greater risk of salmonellosis in experimental animals. The organisms that survive passage through the stomach are able to colonize the middle portions of the ileum on the day of ingestion. Here they attach preferentially to the tips of villi, which they invade and in which they multiply. *Salmonella* strains of a given species vary in their virulence, which is partially determined by their ability to invade nonphagocytic host epithelial cells. Salmonellae have pili-like projections that facilitate insertion of bacterial proteins into epithelial cells following contact. This triggers a cascade that results in uptake of the bacteria by enterocytes or M cells.¹⁶² Localization and persistence of the organisms in the intestinal epithelium and lymph nodes account for shedding, which occurs for 3 to 6 weeks in most cases. The shedding is continual for the first week but then becomes intermittent. Phagocytic cells in the intestinal lymph nodes, liver, or spleen may harbor the organism persistently, even in the absence of shedding. Reactivation of shedding or clinical illness may occur after stress, immunosuppression, concurrent systemic viral infections, and crowding.

Mucosal invasion, host inflammatory response, and resultant GI epithelial injury and sloughing are more common with salmonellosis than with bacterial diarrhea resulting from other kinds of infections. *Salmonella* strains differ in their pathogenicity, which correlates with their ability to attach to and invade mucosa, a property associated with their cell adherence and invasion. However, the extent of injury is not sufficient to explain the amount of fluid loss associated with diarrhea.⁵⁷ Adequate evidence suggests that some salmonellae produce heat-labile enterotoxins, which increase adenyl cyclase. This increase stimulates secretion of fluid by the intestinal mucosa, a process that occurs in other diarrheas associated with noninvasive enterotoxigenic bacteria (see [Fig. 89-8, A](#)).

Endotoxemia or bacteremia may occur during overt enteric infection or in the absence of signs of intestinal illness. Fever, leukopenia, endotoxic shock, and death may result. In surviving animals, focal suppuration with localization of organisms can occur in the biliary tract, kidneys, heart, spleen, meninges, joints, and lungs. A decrease in bacteremia and clearance of organisms from the blood are associated with a rising antibody titer to cell wall O antigen; the flagellar H antigen has no role in protection. Prolonged bacteremia or overwhelming sepsis is usually indicative of compromised host defense mechanisms. Prolonged intermittent bacteremia after salmonellosis is not as common a problem in animals as it is in people with *S. typhi* infection. The K, or capsular, antigen (called Vi for *S. typhi*) of this organism allows it to persist intracellularly for long periods despite adequate host defenses. Virulence plasmids found in some *Salmonella* serotypes enhance their extraintestinal growth and production of bacteremia.^{112,247} For salmonellae to cause bacteremia, they must possess virulence factors allowing them to resist killing by phagolysosomes within leukocytes.

Endotoxemia from overwhelming salmonellosis is associated with various effects on the host and is related to the lipopolysaccharide composition of their cell wall (see Endotoxemia, [Chapter 38](#)). Pooling of leukocytes, erythrocytes, and platelets in the peripheral vasculature; hypoglycemia; complement activation; release of vasoactive amines; and development of disseminated intravascular coagulation (DIC) may occur.

Infectious Diseases of the Dog and Cat, 3rd Edition

39.5.4 Clinical Findings

Clinical findings in salmonellosis vary according to the number of infecting organisms, the immune status of the host, and the complicating factors or concomitant diseases. The syndromes can be artificially divided into gastroenteritis, bacteremia and endotoxemia, organ localization, and persistence of an asymptomatic carrier state.

39.5.4.1 Gastroenteritis

The clinical signs associated with *Salmonella* gastroenteritis vary. Most acute episodes begin within 3 to 5 days of exposure to the organism or after stress in carriers. Very young or old animals show the most severe clinical signs. Fever of 40°C to 41.1°C (104°F to 106°F), malaise, and anorexia are noted initially and are followed by vomiting, abdominal pain, and diarrhea. Cats frequently hypersalivate as a result of persistent vomiting. The diarrhea varies in consistency from watery to mucoid, and fresh blood is present in severe cases. Weight loss and dehydration become evident within several days after the onset of illness. Severely affected animals have pale mucous membranes, weakness, marked dehydration, cardiovascular collapse, shock, and icterus just before death. Central nervous system signs in some animals include hyperexcitability, incoordination, posterior paresis, blindness, and convulsions. Pneumonia can be associated with acute *Salmonella* gastroenteritis. Coughing, dyspnea, and epistaxis are seen in affected animals.

39.5.4.2 Bacteremia and Endotoxemia

Bacteremia and endotoxemia are usually transient subclinical features of *Salmonella* gastroenteritis and become clinically significant in either very young or immunosuppressed dogs and cats. Cats fed a raw-meat diet heavily contaminated with *Salmonella* have developed severe gastroenteritis, septicemia, and death.⁴²⁸

Other dogs and cats may have bacteremia and persistent fever in the absence of GI signs. Affected kittens and puppies younger than 7 weeks may not show a febrile response despite bacteremia or endotoxemia. In severe cases, mental depression, pale mucosae, weakness, tachycardia, hypothermia, and cardiovascular collapse may be seen with or without GI signs. Organ dysfunction from thrombosis or hemorrhagic tendencies can occur from DIC.

39.5.4.3 Organ Localization

Metastatic infection may occur after clinical or subclinical bacteremia. Organisms may localize in particular organ systems for a period before producing overt clinical signs. Localization is most likely to occur in tissues previously damaged or devitalized but may spread to healthy structures. The clinical signs are referable to the organ system of localization. For example, a cat developed pneumonia caused by *S. choleraesuis* without enteric manifestations or positive fecal culture results.³⁷² Abscesses, pyothorax, meningitis, osteomyelitis, and cellulitis are other examples of focal disease.

39.5.4.4 Other Syndromes

Abortion, stillbirth, and birth of weak puppies or kittens may result from in utero infection. Vaginal discharges, placentas, and meconia usually contain *Salmonella*. The bitch or queen generally has prolonged vaginal discharges and delayed postpartum involution. Puppies that survive are weak, unthrifty, and emaciated, and *Salmonella* can be isolated from various organs. Conjunctivitis has been a major

Infectious Diseases of the Dog and Cat, 3rd Edition

manifestation in some infected cats that also have regional lymphadenomegaly and persistent fecal shedding of salmonellae. (See [Chapter 93](#) for an additional discussion of ocular lesions.)

39.5.4.5 Songbird Fever

Seasonal bird migrations have been associated with *S. typhimurium* and an acute febrile illness in cats that usually lasts 2 to 7 days. Reports have been documented from wild birds migrating in the northeastern United States and Sweden.⁴⁴² Affected cats have primarily been outdoors and preyed on birds or frequented bird feeders. Clinical signs include acute depression, anorexia, fever (40°C to 40.6°C [104°F to 105°F]), diarrhea, which is often hemorrhagic, and variable vomiting. Recovery usually is rapid, but in some cases normal feeding behavior does not return for several weeks. Mortality may be as high as 10%, and other diseases causing immunosuppression may increase this number. Therapy for and prevention of this syndrome are the same as for other *Salmonella* infections.

39.5.4.6 Subclinical Infections and Clinical Recovery

Only a small proportion (less than 10%) of infected animals die during the acute stages of salmonellosis. Dogs and cats infected with few organisms and those that have otherwise normal defense mechanisms have transient or no clinical illness. Some cats may have a persistent chronic febrile illness characterized by anorexia and lethargy without diarrhea. Animals affected by acute diarrhea usually recover after 3 to 4 weeks. Rarely, chronic or intermittent diarrhea that lasts for up to 8 weeks is reported.⁸⁴ Recovered and clinically normal animals usually shed the organisms for up to 6 weeks.

39.5.5 Diagnosis

Salmonellosis should be suspected in animals with any acute or chronic GI illness. It has frequently been overlooked in favor of the more notorious viral enteritis caused by canine parvovirus or coronavirus and feline panleukopenia virus. The clinical and pathologic features of these diseases may be indistinguishable from those of salmonellosis (see Clinical Findings, [Chapters 8](#) and [10](#)).

39.5.5.1 Clinical Laboratory Findings

Hematologic abnormalities vary depending on the stage of illness. Nonregenerative hypochromic anemia, lymphopenia, thrombocytopenia, neutropenia with a left shift, and toxic leukocytes are found in animals with systemic disease and endotoxemia. Bacterial rods may be found in the leukocytes of dogs or cats with overwhelming sepsis. A mature neutrophilic leukocytosis is more characteristic of chronically infected animals or animals with localization of infection in a particular organ system. Prolonged coagulation test times are apparent in animals with severe DIC.

Biochemical abnormalities are usually present only in animals with severe clinical illness. These abnormalities include hypoproteinemia, especially hypoalbuminemia, hypoglycemia, and moderate prerenal azotemia. Dogs with salmonellosis have had electrolyte abnormalities, hyponatremia, and hyperkalemia typical of primary hypoadrenocorticism.

Infectious Diseases of the Dog and Cat, 3rd Edition

39.5.5.2 Bacterial Isolation

Isolation of *Salmonella* organisms is the most definitive means of confirming infection. However, mere isolation from the oral cavity, vomitus, or feces does not indicate that the organisms are causing clinical disease, because the prevalence of subclinical carriers in dog and cat populations is high. Animals recovering from clinical salmonellosis shed organisms for at least 4 to 6 weeks, and shedding can be reactivated by stress or recurrent illness.

Finding organisms in samples of normally sterile secretions or body fluids, such as blood, urine, synovial fluid, transtracheal washings, cerebrospinal fluid (CSF), and bone marrow, may allow a definitive diagnosis of systemic salmonellosis to be made from chronically febrile animals or during the acute phases of illness. Samples for culture should be taken from the liver, spleen, bone marrow, lung, mesenteric lymph nodes, and intestinal tract at necropsy. The gallbladder and bile do not appear to be consistent sites of localization of infection in animals, although they are in people infected with *S. typhi*.

Normal culture results do not necessarily eliminate the possibility of infection, because it is difficult to isolate salmonellae in the presence of other organisms. Specimens from normally sterile tissues, such as blood, bone marrow, joint fluid, and CSF, can be cultured on ordinary media. Samples taken from the oral cavity or bowel, both of which have a high concentration of commensal organisms, must be cultured on special media. Treated animals should not be considered free of infection during monitoring until at least three successive attempts at culture have been made over 2- to 3-week intervals. To avoid losing organisms during shipment to a laboratory, fresh fecal specimens should be placed in Amies transport medium with charcoal.

Enrichment broths (e.g., selenite and tetrathionate) are used to increase the yield and inhibit growth of competing organisms. Numerous improved plating media have been developed.^{90,376} Atmospheric oxygen can be damaging to *Salmonella*. Commercial media (SPRINT, Oxoid Ltd, Basingstoke, England) is available that contains oxygen scavengers to facilitate cultivation.²⁰⁷ After 24 hours, subculturing is performed on an inhibitory medium, such as deoxycholate, that favors the growth of *Salmonella*. After isolation, salmonellae are identified by Gram staining, motility, and biochemical reactions. They ferment certain sugars, including glucose (but not lactose) and react positively with substances such as urea, indole, and methyl red.

39.5.5.3 Immunologic and Genetic Identification

Other nonculture methods can help identify infected hosts. The real-time PCR method has been used to detect salmonellae in canine fecal specimens.²⁵¹ In addition an ELISA with monoclonal antibody (*mab*) has been used to detect *Salmonella* antigens in urine of bacteremic people.

358

39.5.5.4 Serologic Testing

Demonstration of a rise in serum antibody titer to O and H antigens has been used in human medicine as a less specific means of detecting clinical illness. Not all subclinically infected dogs and cats have positive serologic titers, thus serologic testing is not an accurate means of detecting carriers. Cats respond consistently with increased titers only when they are clinically ill. For these reasons, culture of body fluids or secretions is a simpler and more definitive means of making a diagnosis.

359

Infectious Diseases of the Dog and Cat, 3rd Edition

39.5.5.5 Cytologic Examination

Cytologic examination is helpful in detecting invasive GI pathogens in diarrheal illnesses. The presence of leukocytes in feces can identify diseases that cause disruption of the intestinal mucosa. A wet mount is prepared by mixing small flecks of mucus with a drop of new methylene blue on a microscope slide and placing a coverslip on the mixture. The absence of fecal leukocytes indicates a viral, mild bacterial, or nonspecific diarrhea that does not require extensive therapy. The presence of large numbers of leukocytes is typical of acute salmonellosis and other forms of diarrhea that cause extensive mucosal disruption. These cases usually require intensive parenteral fluid and antibiotic therapy.

39.5.6 Pathologic Findings

Gross lesions are found at necropsy in only a small percentage of infected animals that develop severe clinical illness. Pale mucous membranes and dehydration accompany a diffuse mucoid to hemorrhagic enteritis. Lesions in the intestinal mucosa vary from catarrhal inflammation to mucosal sloughing with extensive denudation of the gut. GI lesions may be extensive but are usually confined to the distal small bowel, cecum, and colon. Diffusely scattered petechial to ecchymotic hemorrhages present throughout most organ systems are associated with focal thrombosis and necrosis. A serohemorrhagic effusion may be present in the abdominal cavity, with fibrin adhered to inflamed viscera. The lungs are frequently edematous or consolidated, and mesenteric and peripheral lymph nodes are enlarged and hemorrhagic.

Histologically, variable lesions are a fibrinous to fibropurulent pneumonia, multifocal necrotizing hepatitis and splenitis, and suppurative meningitis, all of which are associated with necrotic intestinal lymphadenitis and hemorrhagic ulcerative gastroenteritis. Histologic or cytologic examination may reveal that bacteria have disseminated to many organs, including the bone marrow, spleen, and lymph nodes.

39.5.7 Therapy

Appropriate therapy for canine and feline salmonellosis varies according to the type and severity of clinical illness. Acute *Salmonella* gastroenteritis without systemic signs is best treated with parenteral polyionic isotonic fluids to replace losses from vomitus and diarrhea. Fluids can be administered orally when vomiting is not a problem. Hypertonic glucose-containing solutions have been effective in reversing fluid loss in infectious diarrhea (see [Chapter 89](#)). Transfusion of plasma may be more beneficial than fluid therapy when mucosal disruption and increased GI permeability lower serum albumin concentration to less than 2 g/dl.

Prostaglandin inhibitors such as indomethacin have been effective in reducing fluid losses in animals with experimentally induced *Salmonella* gastroenteritis. Increased net water loss in the lower bowel results from increased intestinal secretion induced by bacterial endotoxin and mediated through prostaglandin synthesis. Prostaglandin inhibitors must be used early in the disease to be effective and must be used cautiously if GI hemorrhage is severe. Flunixin meglumine has been more commonly administered in dogs and cats, but GI bleeding and renal failure have been associated factors.

Paradoxically, osmotically active laxatives such as lactulose have been recommended for treating acute *Salmonella* gastroenteritis. As a nonabsorbable sugar, lactulose produces osmotic diarrhea through the formation of acid metabolites in the distal small bowel and colon. Shortened transit time and an acidic environment shorten the survival time of *Salmonella* organisms. Such therapy should be used only in unresponsive cases in which fluid deficits have already been corrected.

Infectious Diseases of the Dog and Cat, 3rd Edition

Routine antibiotics reported to be effective against *Salmonella* include chloramphenicol, trimethoprim-sulfonamide, and amoxicillin. Aminoglycosides such as gentamicin and amikacin may be considered when bacterial resistance is anticipated, but the risk of renal toxicity precludes their routine use. Isolates are generally sensitive to the quinolones and imipenem; however, high cost and the desire to reduce the development of antimicrobial resistance make these second choices unless overwhelming sepsis is apparent. Variable resistance to erythromycin, clindamycin, ampicillin, cephalixin, sulfonamides, or nitrofurans is reported. Resistance is greatest to streptomycin, tetracycline, and sulfonamides alone. Unfortunately, the in vivo response of *Salmonella* to antibiotics does not always correlate with the results of in vitro testing. For example, a cat with salmonellosis that did not respond to amoxicillin or cephalixin was effectively treated with cephalixin.⁸⁴

Antibiotic therapy has not been advocated for treating animals with uncomplicated *Salmonella* gastroenteritis but has been recommended for animals with concurrent signs of nonenteric (systemic) infection or histories of immunosuppression (see [Table 39-2](#)). Studies in human patients have indicated that routine antimicrobial use in treating salmonellosis induces drug-resistant strains and prolongs the convalescent excretion period. However, this widely held view has been questioned in studies that demonstrate effective eradication of *Salmonella* from people and animals by combined antibiotic therapy. One hypothesis is that antimicrobial therapy may suppress endogenous flora that normally inhibits intestinal colonization by *Salmonella* species. Competitive exclusion is a procedure that has been used on farms to reduce the carriage of enteric salmonellae by livestock. Animals are treated with antimicrobials to eliminate the *Salmonella* followed by oral administration of a probiotic. Probiotics (feed supplements containing live organisms that help reestablish the intestinal flora) have not been used in dogs, but in a controlled study in *Salmonella*-infected horses, no benefits were found.³³⁹

Another inherent problem with routine antibiotic administration for *Salmonella* gastroenteritis is that infecting organisms may acquire transferable (plasmid-mediated) resistance. An increased prevalence of transferable resistance has been demonstrated among *Salmonella* isolates from dogs, cats, and people. The fluoroquinolones have a reduced tendency to produce plasmid-mediated resistance in bacteria compared with other antibacterials; however, fluoroquinolone-resistant salmonellae have been found in human outbreaks associated with frequent use of the drug in hospitals.³³⁰ Similar concerns have been addressed for veterinary isolates.³⁵⁴ Other disadvantages of routine antibiotic therapy for salmonellosis are that it may enhance susceptibility to infection or activate clinical illness in a latent carrier.

Animals with more severe signs of endotoxemia or bacteremia should be treated differently from those with simple gastroenteritis. Plasma transfusions of at least 250 ml for dogs larger than 15 kg have reduced mortality in those dogs that had been given *Salmonella* endotoxin. Equal volumes of isotonic fluid or smaller volumes of plasma were not helpful. Like untreated dogs, plasma-treated dogs developed leukopenia, thrombocytopenia, and extensive tissue injury, but they had better survival rates. Dogs with experimentally induced endotoxic shock were protected by infusion of *mabs* directed against the endotoxic lipid A cell wall component of *Salmonella*.³⁷⁷ A commercially available polyclonal antiserum is available for this purpose (see discussion of antiendotoxin serum in Therapy, [Chapters 8](#) and [38](#)).

359

360

39.5.8 Prevention

Prevention of salmonellosis in dogs and cats can be frustrating because of the tendency of some animals to develop a chronic subclinical carrier state or latent infection. Nontyphoid salmonellae that infect pets are also harbored by many other animals and persist in the environment, making eradication difficult.

Infectious Diseases of the Dog and Cat, 3rd Edition

Hygiene and isolation of individual pets should be enforced during hospitalization because of the highly infectious and contagious nature of salmonellosis. To prevent development and spread of infections in a veterinary teaching hospital, newly admitted horses were only placed in stalls where *Salmonella* had been previously isolated, after two cycles of cleaning and disinfection.⁶ Infection from food sources can be minimized by using commercially available heat-processed products. Proper sanitation during handling and storing of processed foods is also important, because they frequently become contaminated by contact with utensils, rodents, or insects. Meat, eggs, and dairy products given as food should be stored or thawed at temperatures lower than 4.4°C (40°F) and should be cooked to internal temperatures of at least 74°C (165°F). Imported commercial dog chews made from animal hides have been found to contain *Salmonella* organisms.⁴⁹⁵

Cages in hospitals, kennels, or catteries should be routinely cleaned and disinfected between uses by different animals (see [Chapter 94](#)). Phenolic compounds or household bleach (diluted 1:32, or 4 oz per gallon of water) can be applied as surface disinfectants, but their contact with cats should be avoided. Animals brought into a group confinement situation should be segregated if they have or develop diarrhea or vomiting. Food dishes and utensils should be cold disinfected, or preferably autoclaved, between uses. Disposable dishes can simply be thrown away. Endoscopic equipment, which is shown to be a source of infection in human hospitals, should also be properly disinfected (i.e., subjected to ethylene oxide gas or immersed in glutaraldehyde [2%] or formalin [20% for a minimum of 1 hour]). The equipment must be thoroughly aerated or rinsed before use (see [Chapter 94](#)).

Human carriers of nontyphoid *Salmonella* may transmit the infection as a reverse zoonosis, a possibility that should not be overlooked in an animal-holding facility that has a recurrent problem with salmonellosis. Long-term boarders or blood donors should not be housed with the transient hospital population because they may be exposed and become future sources of *Salmonella* infection.

39.5.9 Public Health Considerations

Clinical signs of animal-acquired salmonellosis in people include abdominal tenderness, nausea, vomiting, and diarrhea accompanied by fever, myalgia, headache, and dehydration. Like animals, people may develop localized or septicemic forms of illness, depending on their immunocompetence.

Salmonellosis is a disease of major zoonotic importance. All *Salmonella* organisms, except those causing human typhoid fever (*S. typhi* and *S. paratyphi*), infect people and animals. Considerable emphasis has been placed on foodborne outbreaks of nontyphoid salmonellosis in people through contaminated products of animal origin. Foods such as meat, eggs, or milk products that have been improperly stored, prepared, or handled before consumption are most often incriminated. Sporadic pet-associated infections have not received as much attention. Dogs have been recognized as important vectors for non-foodborne infections in people because of the canine habits of coprophagy and ingesting carrion coupled with long-term shedding of organisms and close proximity to people. Infants and older adults are especially prone to infections from pets.³³⁸ Dogs and horses have the greatest zoonotic potential for those with occupational exposure. Reptiles and amphibians are most frequently incriminated in pet-associated cases.^{97,216} Outbreaks in people caused by exposure to infected horses have been commonly reported.⁴⁵³ Contact with feces from infected pets has been an important source of exposure for young children. Cats, proved to be important but less frequently infected reservoirs, shed organisms orally, conjunctively, and focally. Thus they may contaminate their food, fur, or water source, any of which may serve as a source of infection for people. Salmonellosis caused by multidrug-resistant organisms occurred in three small animal practices where inadvertent contamination of the environment by cats with

Infectious Diseases of the Dog and Cat, 3rd Edition

diarrhea caused outbreaks of infection in people and cats in the facilities.¹⁷ Inadvertent ingestion of animal feces or food contaminated by feces likely occurred as a result of sub optimal hygiene in and sanitation of the veterinary facilities. The use of antimicrobial agents in the animals likely contributed to the drug-resistant strains. People who handle raw-meat diets or who are exposed to the feces of domestic or wild dogs or cats being fed such diets are also at increased risk of exposure. *S. ser enteritidis* infections are largely associated with egg products. Multidrug-resistant *S. ser typhimurium* strain DT 104, which has been a prevalent foodborne animal strain that infects people in the United Kingdom and the United States, has also been found in cats, dogs, and other nonfood animals.^{14,366} Most isolates possess chromosomally encoded resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline, and some isolates are resistant to quinolones and trimethoprim.³⁸²

To reduce the risk of infection from pets, hands should be thoroughly washed with soap and water after handling animals or fomites such as animal bedding, footwear, or clothing contaminated with feces. Detergents and household bleach added to the laundry eliminate the organisms in these fomites.

Of increasing concern is the frequency with which antibiotic-resistant *Salmonella* strains have been isolated from dogs and cats. Most of the resistance is plasmid mediated and intensified by indiscriminate or frequent administration of antibiotics by veterinarians.^{76,167} Antibiotic resistance has made recently acquired salmonellosis more difficult to treat in people. Quinolone resistance has been feared and reported in salmonellae in the United States, necessitating the restricted use of these drugs in food animals.¹⁹⁹ In the United Kingdom, antimicrobial resistance has been documented in salmonellae from food animals and their environment.²²⁹ *Salmonella* infections have been more frequent and severe in people infected with HIV.

39.6 SHIGELLOSIS

Craig E. Greene

39.6.1 Etiology

Shigella is a genus of nonmotile gram-negative bacteria that are morphologically indistinguishable from other enterobacteria and cause a diarrheal condition known as *bacillary dysentery* in apes and people. On the basis of biochemical and serologic properties, they are divided into four serogroups: *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*. Each group is further divided into numerous subserotypes that vary in pathogenicity. Shigellae are not as environmentally resistant as salmonellae; they cannot survive a temperature of 55°C for longer than 1 hour, and they are destroyed by dilute (1%) phenol within 30 minutes. They are susceptible to inactivation by sunlight and acid pH but can remain viable for a few days in nonacidic stools maintained in the dark. Shigellae survive best in dried fecal matter on cloth that is kept in a dark, moist place. Because of their short survival time, the carrier host is most important in maintaining these organisms in nature.

360

361

39.6.2 Epidemiology

Shigellae are principally primate pathogens, causing severe hemorrhagic enteritis (dysentery). The disease, which spreads primarily via fecal-oral contact, is most commonly a problem in nonhuman primate colonies with substandard sanitation or hygiene practices. Although rare, waterborne outbreaks in people may occur with sewage contamination of domestic water supplies.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dogs may become infected after contamination of their food or water supplies with infected human feces. Because of their coprophagous habits, pets may become exposed in areas with improper sewage disposal. Once they contract an infection, dogs are probably not carriers and only transiently excrete the organisms. Cats have not been reported to be naturally infected.

39.6.3 Pathogenesis

Shigellae may damage the body because of a gram-negative endotoxin that is produced. Shiga toxin is one of the most toxic biologic agents when given systemically. Certain organisms (e.g., *S. dysenteriae* type 1) produce enterotoxins that increase intestinal fluid secretions and can cause ulceration. Shigellae probably produce diarrhea by intestinal epithelial cell invasion with resultant necrosis and hemorrhage and by effects of the Shiga toxin. Shiga toxin is also synthesized by and may be an important virulence factor of other pathogenic bacterial species. Systemic manifestations of the toxin in infected people include DIC with renal failure, thrombocytopenia, and microangiopathic hemolytic anemia.

39.6.4 Clinical Findings

In primates the organism causes severe hemorrhagic, mucoid, large-bowel diarrhea. Lesions are usually ulcerative, and they spread from the distal to the proximal colon with time. In children and, although rarely, in adults, septicemia may develop with or without diarrhea. Unlike primates, dogs are relatively resistant and cats are highly resistant to infection with *Shigella*. Organisms have been isolated from a small number of clinically normal dogs, but they have not been directly implicated as a cause of diarrhea in this species.

39.6.5 Diagnosis

Demonstration of organisms in culture is essential to differentiate *Shigella* enterocolitis from diarrhea caused by other bacteria. Because of the fastidious nature of the organism, samples collected on swabs should be transported to the laboratory immediately and not be exposed to sunlight. Cytologic examination of the stool reveals large numbers of inflammatory cellular exudates associated with invasion of the bowel wall by *Shigella*.

39.6.6 Therapy

Symptomatic treatment with parenteral fluids and antimicrobial therapy are similar to those in salmonellosis and enteropathogenic diarrhea (see [Table 39-2](#)). Unlike *Salmonella* organisms, many shigellae are still sensitive to ampicillin, sulfonamide, tetracycline, and streptomycin. Antimotility therapy was detrimental to people with experimentally induced shigellosis.⁸⁹

39.6.7 Prevention

Control measures for shigellae are very similar to those outlined for salmonellae. Shigellosis is easier to prevent in dogs and cats than salmonellosis because the reservoir of *Shigella* organisms is restricted to the primate host.

39.7 YERSINIOSIS

Craig E. Greene

Infectious Diseases of the Dog and Cat, 3rd Edition

39.7.1 Etiology and Epidemiology

Three major pathogenic members of the genus *Yersinia* infect dogs and cats: *Yersinia enterocolitica*, *Yersinia pseudotuberculosis*, and *Yersinia pestis*. (*Y. enterocolitica* and *Y. pseudotuberculosis* are discussed in this section, and *Y. pestis*, the cause of plague, is discussed in [Chapter 47](#).) *Y. enterocolitica*, which is 0.5 to 1 μm \times 1 to 3 μm , is a motile, gram-negative, facultative coccobacillus that causes an enterocolitis in people. An unusual feature of this bacterium is that it replicates in culture at refrigeration temperatures, which allows its selective growth in the laboratory and refrigerated food. Heating food to 60°C for a few minutes kills the organism. The bacterium, which has been isolated from the feces of various domestic and wild animal reservoirs and the environment, has a worldwide distribution. The prevalence of isolation of this organism from animals increases in colder months, perhaps because of its affinity for colder temperatures. The organism causes illness by invading many body tissues and elaborating a heat-stable enterotoxin. Virulence-related factors of the organism appear primarily at lower temperatures, making human acquisition of infection more likely through contamination of the environment or food rather than directly from the carrier host. People appear to be unnatural hosts for this organism because they develop fever, diarrhea, abdominal pain, septicemia, or skin rashes, all signs that closely mimic those of acute appendicitis. Nonsuppurative arthritis may develop as a sequela after recovery from GI illness. Conditions associated with iron overload appear to predispose the host to systemic spread of the organism.

Y. pseudotuberculosis is a cause of enteritis in many animals, especially during the wet, cold winter and spring months. Various animals, including birds, rodents, cats, and pigs, have been incriminated as reservoir hosts. People are more severely affected and develop mesenteric lymphadenitis and septicemia.

39.7.2 Clinical Findings

Because *Y. enterocolitica* has been isolated from feces of clinically normal dogs and cats, it is thought to be a commensal organism. It has also been isolated from people with clinical illness who presumably contracted the infection through contact with the excreta of infected household pets. Experimental infections in adult dogs have produced no clinical illness, despite periodic fecal shedding for 52 days and recovery of the organism from mesenteric lymph nodes and other tissues.⁴²² Feeding of contaminated raw pork produced subclinical transfer of infection to dogs.¹⁵⁵ Infected dogs have developed resistance to reinfection. *Y. enterocolitica* has also been cultured from the feces of young dogs with symptomatic GI illness.^{105,337} The syndrome has been characterized by a several-week history of diarrhea associated with increased frequency of stools, tenesmus, blood, and mucus. In contrast to infected people, infected dogs were not systemically ill. Dogs and cats may be asymptomatic carriers of *Y. pseudotuberculosis*. A Persian cat infected with *Y. pseudotuberculosis* developed anorexia, abdominal discomfort and weight loss, and dehydration.²¹² In a 4-month-old Rottweiler pup infected with *Y. enterocolitica*, sudden death was caused by transmural myocarditis. Multifocal granulomatous hepatitis was apparent. Bacteremic spread from the bowel to the liver and the systemic circulation was suspected.⁴⁹¹

361

362

39.7.3 Diagnosis

Diagnosis of yersiniosis has been based on culture of the organism from the feces or deeper tissues of affected animals. As with other enteropathogenic bacterial infections, mere isolation from the intestinal tract may not be diagnostic of pathogenicity because the organism can be found in clinically healthy animals. Isolation of the organism from deeper tissues such as blood, urine, lymph nodes, wounds, or abscesses is more meaningful.

Infectious Diseases of the Dog and Cat, 3rd Edition

Yersinia are not usually cultivated on conventional media because they produce small colonies that are later overgrown by normal floral organisms. A selective medium containing cefsulodin, irgasan, and novobiocin greatly improves the ability to isolate *Yersinia* from enteric specimens. Serotyping of *Yersinia* strains is similar to that of *Salmonella*. In systemically affected individuals, small, pale-yellow abscesses are scattered on the surface and throughout the parenchyma of the liver and spleen. Histologic examination in one clinically affected dog with *Y. enterocolitica* infection revealed a chronic enteritis with mononuclear and plasma cell infiltrates in the intestinal mucosa and mesenteric lymph nodes.¹⁰⁵ A cat with *Y. pseudotuberculosis* infection had focal microabscesses with microthrombosis in the liver and spleen.²¹²

39.7.4 Therapy

Yersiniosis therapy should be attempted in younger dogs or cats from whose feces the organism has been isolated and that have diarrhea or are in contact with people with confirmed infections. The organism is usually sensitive to routine dosages of chloramphenicol, tetracycline, gentamicin, cephalosporins, and trimethoprim-sulfonamides (see Table 39-2). Penicillin and its derivatives are not usually effective in routine dosages. As with other enteropathogenic bacteria, consumption of raw dairy or meat products or of wildlife carcasses predisposes the animals to infection and should be avoided. Raw meat should not be fed to pets.

39.7.5 Public Health Considerations

Outbreaks of gastroenteritis have been reported in people exposed to infected pet dogs.¹⁸² Young children who drank water from puddles and played in a sandbox frequented by a stray cat became infected with *Y. pseudotuberculosis*.¹⁵⁹ The organism could be isolated from the water, sand, and soil. Precautions should be taken to avoid exposing young children to these types of situations. As mentioned, raw meat should not be fed to pets.

39.8 PLESIOMONAS SHIGELLOIDES INFECTION

Craig E. Greene

A motile, gram-negative facultatively anaerobic bacterium in the family Vibrionaceae, *Plesiomonas shigelloides* is a zoonotic cause of acute diarrhea in people. (Rarely, infection spreads systemically in immunocompromised people.) This water- and soil-associated organism is found in temperate and tropical freshwater environments and is prevalent in the intestinal tract of aquatic animals. The usual means by which people acquire infection is through ingestion of water or foods contaminated by feces from infected animals such as shellfish, poultry, livestock, and dogs or cats.³ Feeding of fish, shellfish, or aquatic foodstuffs to dogs or cats may be a source for infection.²¹⁷

Diarrheic illness has sometimes been attributed to *P. shigelloides* in dogs and cats^{120,217}; however, it is found in the feces of clinically healthy research cats⁴¹⁸ and was isolated from fecal swabs and postmortem material from cats.²⁸ In contrast, most infected people develop diarrhea that can vary from mildly self-limiting to diarrhea that is severe and has a bloody mucoid consistency. Bacteremia, which can result in embolic spread to many organs, generally occurs in immunocompromised people. Similar serotypes have been isolated from people and associated cats, suggesting zoonotic transmission.^{168a} The organism is often susceptible to trimethoprim-sulfonamides,

Infectious Diseases of the Dog and Cat, 3rd Edition

quinolones, cephalosporins, and penicillin-clavulanate combinations. Should the organisms be found in the feces of a diarrheic dog or cat, another cause should be investigated.

39.9 TYZZER'S DISEASE

Boyd R. Jones

Craig E. Greene

39.9.1 Etiology

Tyzzler's disease is caused by *Clostridium piliforme* (formerly "*Bacillus piliformis*"), a spore-forming, gram-negative obligate intracellular parasite measuring $0.5\ \mu\text{m} \times 10$ to $40\ \mu\text{m}$ that moves by means of peritrichous flagella. RNA sequences of this organism are closely related to those of the clostridia, so the new name—*C. piliforme*—has been adopted. Originally described as a disease of rodents, it is now known to affect a wide range of animals. Reports of spontaneous disease in dogs and cats have been described.*

* References 32, 40, 226, 246, 249, 298, 314, 357, 358, 364, 392, 393, 493.

39.9.2 Epidemiology

C. piliforme, which appears to be a commensal organism of the intestinal tracts of laboratory rodents, is found on fecal cultures of normal and diseased animals. Clinical illness in rodents seems to be precipitated by stress, such as crowding, unsanitary conditions, weaning, or transportation and irradiation, glucocorticoid therapy, or other forms of immunosuppression.

Dogs and cats may acquire infection by contact with or ingestion of rodent feces containing bacterial spores, although such interspecies transmission has never been reported. Experimental disease has been difficult to produce in healthy dogs and cats. Most feline cases have occurred in laboratory-reared cats, some with known contact with rodents. It is possible that dogs and cats harbor the organism.

A majority of infected animals have had naturally or experimentally induced immunosuppressive diseases such as feline leukemia, feline panleukopenia, feline infectious peritonitis, and canine distemper.^{214,215,224} One group of affected kittens had familial lipoprotein lipase deficiency and were persistently lipidemic.²²⁶

In experimental studies the severity of the disease has been enhanced by overcrowding, administration of glucocorticoids or cyclophosphamide, splenectomy, irradiation, partial hepatectomy, and mononuclear-phagocyte blockade.

39.9.3 Pathogenesis

The pathogenesis of Tyzzler's disease is uncertain. The mechanisms by which *C. piliforme* attaches to and enters host cells are unknown. Endogenous or exogenous infection is followed by local proliferation of organisms in the intestinal epithelial cells. After stress or immunosuppression of the host, organisms spread by portal circulation to the liver. Colonization in the hepatic parenchyma results in multifocal periportal hepatic necrosis, presumably as the result of an unidentified toxin.

Infectious Diseases of the Dog and Cat, 3rd Edition

39.9.4 Clinical Findings

Clinical signs have been relatively consistent among dogs and cats in which the disease has been reported. The onset of lethargy, depression, anorexia, and abdominal discomfort is very rapid. Hepatomegaly and abdominal distention are followed by hypothermia, with the animal becoming moribund, resulting in death within 24 to 48 hours. Diarrhea has been infrequent; scant amounts of pasty feces are more characteristic. Icterus has been apparent in some animals, especially cats.

39.9.5 Diagnosis

Because of the rapidly fatal course of Tyzzer's disease, diagnosis usually has been made by gross examination of specimens collected at necropsy. Just before death, marked elevations of alanine transaminase activity have been found. Characteristic findings are multiple whitish-gray to hemorrhagic foci, 1 to 2 mm in diameter, on the capsule and cut surface of the liver (Fig. 39-8). Similar lesions may be apparent on other viscera. The intestinal mucosa may be thickened and congested in the region of the terminal ileum and proximal colon. Foamy, dark-brown feces are usually present in the lumen, and mesenteric lymph nodes are generally enlarged.

Histologic findings usually include multifocal periportal hepatic necrosis and necrotic ileitis or colitis; other tissues, such as the myocardium, may be affected in some animals. Infiltrates of neutrophils and mononuclear cells are usually present at the margins of necrotic lesions. Numerous intracellular filamentous organisms are only faintly visible by hematoxylin and eosin stain in the hepatocytes at the margins of necrotic lesions and in the intestinal epithelial cells. Special stains such as Giemsa stain or Warthin-Starry or Gomori silver stain must be used to confirm the morphology of the organisms, which have a characteristic beaded appearance (Fig. 39-9). The organisms also can be demonstrated in methylene-blue-stained impression smears made from lesions in fresh tissues. Filamentous and spore forms of *C. piliforme* have been found. *C. piliforme* cannot be isolated on artificial medium that lacks living cells and so far has been cultured only in eggs or cell cultures.⁴¹⁹

Serologic methods have become a common tool for diagnosing latent infections in rodent colonies. *Mab*-based tests have aided investigation of the disease. Flagellar antigens have been purified from *C. piliforme* from different species, and significant antigenic differences exist. Nevertheless, such serologic tests could be applied to investigations of the dog and cat.

39.9.6 Therapy and Prevention

Thus far, treatment of Tyzzer's disease has not been successful, because affected animals die before it can have an effect. Antibiotic efficacy is undetermined. Success has been achieved with formalin-inactivated vaccines, which produce immunity to infection in mice. When possible, predisposing factors that have been associated with infection in dogs and cats should be identified and avoided.

Fig 39-8 Tyzzer's disease in kitten. Multifocal white spots on liver are hepatocellular necrosis. Similar-appearing lesions visible through pericardial sac are caused by focal myocarditis. (From Jones BR, Johnstone AC, Hancock WS. 1985. Tyzzer's disease in kittens with familial primary hyperlipoproteinaemia, *J Small Anim Pract* 26:411-419.)

39.10 CLOSTRIDIUM PERFRINGENS– AND CLOSTRIDIUM DIFFICILE–ASSOCIATED DIARRHEA

Stanley L. Marks

Elizabeth J. Kather

Diarrhea in dogs is a common problem facing the small animal practitioner, and bacterial enteropathogens play an important role in many cases.¹⁷⁸ *Clostridium perfringens* and *Clostridium difficile* are two of the most commonly incriminated bacteria in canine diarrhea^{56,248,361,459,178}; however, it is important to appreciate that these bacterial species are but a small representation of putative pathogenic enteric bacteria.

Clinical signs associated with *C. perfringens* and *C. difficile* infections can range in severity from a mild, self-limiting diarrhea to a potentially fatal acute hemorrhagic diarrheal syndrome.⁵⁶ Clinical documentation of clostridial-associated diarrhea in dogs is clouded by the presence of these organisms existing as normal constituents of the indigenous intestinal microflora. In addition, isolation rates for *C. perfringens* and *C. difficile* are often similar in diarrheic and nondiarrheic dogs. Canine fecal enteric panels, which involve fecal cultures and toxin assays, are expensive (\$70 to \$100), are time consuming, and require technical expertise. Most small animal veterinarians do not have the facilities or expertise to perform these tests, which involves mailing fecal specimens to commercial veterinary diagnostic laboratories for evaluation (see [Appendix 5](#), Laboratory Testing of Infectious Diseases of Dogs and Cats). No universal consensus exists among veterinary diagnostic laboratories as to which diagnostic assays should be used. This problem is compounded by the lack of validations for sensitivity and specificity of commercial toxin assays commonly used in the dog. The indications for performing fecal enteric panels on diarrheic dogs are poorly defined, resulting in indiscriminate testing and misinterpretation of results. The

363

364

Infectious Diseases of the Dog and Cat, 3rd Edition

results of fecal cultures may take up to 72 hours to complete, and many dogs are treated with antibiotics indiscriminately before results of fecal cultures or toxin assays are available. In addition the resolution of clinical signs of diarrhea is often wrongly equated with eradication of the “incriminating” pathogen.

Fig 39-9 Hepatocytes at margins of necrotic focus in Tyzzer's disease. Bacteria resembling *C. piliforme* (arrows) are present within viable cells and extracellularly on necrotic tissue (toluidine blue, $\times 1500$). (From Jones BR, Johnstone AC, Hancock WS. 1985. Tyzzer's disease in kittens with familial primary hyperlipoproteinaemia, *J Small Anim Pract* 26:411-419.)

39.10.1 *Clostridium perfringens*-Associated Diarrhea

39.10.1.1 Etiology

The anaerobic, gram-positive, spore-forming bacillus *C. perfringens* may be one of the most widespread pathogenic bacteria, inhabiting the GI tract of people and animals as well as terrestrial and marine environments.⁴¹⁰ The organism is divided into five biotypes, A to E, based on the possession of one or more of four major toxin genes (Table 39-8): alpha (α), beta (β), iota (ι), and epsilon (ϵ).

Each biotype may also express a subset of at least 10 other established toxins, including *C. perfringens* enterotoxin (CPE). Although all five types can harbor the enterotoxin gene (*cpe*), the global distribution of enterotoxigenic strains is relatively low (approximately 5%), with the majority of strains belonging to type A.^{245,414,463} Virtually all strains isolated from dogs are type A, with only one published report documenting a type C infection in five cases of canine peracute lethal hemorrhagic enteritis.^{22,299} A published study evaluating 843 *C. perfringens* isolates collected from 103 dogs revealed that all isolates tested were type A,

Infectious Diseases of the Dog and Cat, 3rd Edition

with 15% harboring the *cpe* gene.²⁸⁸ Enterotoxigenic *C. perfringens* type A has been associated with human food poisoning and sporadic diarrhea, canine acute and chronic, large and small bowel diarrhea, and an acute hemorrhagic diarrheal syndrome.^{56,288,300,386} Although several studies have shown an association between the immunodetection of CPE in fecal specimens and canine diarrhea, the pathogenesis of *C. perfringens*–associated diarrhea (CPAD) in dogs is not fully understood; CPE is also detected in up to 14% of nondiarrheic dogs.^{288,456,485} In addition, numerous other virulence factors such as the β 2 toxin may also play a role in diarrhea. These virulence factors may explain why the isolation of nonenterotoxigenic type A strains from a diarrheic specimen does not preclude involvement in disease. *C. perfringens* β 2 toxin has been associated with necrotic enteritis in piglets and typhlocolitis in horses.^{163,166,198} The role of β 2-toxigenic *C. perfringens* in dogs is less well understood; only a single study evaluating 24 isolates collected from diarrheic dogs has been published to date.⁴⁴⁸ In the study, isolates were positive for the *cpe* gene (33%), the β 2-toxin gene (33%), or both (17%); however, interpretation of the results of that study was difficult because of the small number of dogs and lack of a nondiarrheic control population.⁴⁴⁸ The presence of the β 2-toxin gene was evaluated in 269 *C. perfringens* isolates obtained from 24 diarrheic and 44 nondiarrheic dogs. β 2-toxigenic *C. perfringens* was isolated from 22% and 15% of diarrheic and nondiarrheic dogs, respectively, providing no support for the role of β 2-toxigenic *C. perfringens* in canine diarrhea to date.

Table 39-8 Typing Scheme for *Clostridium perfringens*

TYPE	MAJOR TOXIN				ENTEROTOXIN
	α	β	I	ϵ	
A	+	–	–	–	+/-
B	+	+	–	+	+/-
C	+	+	–	–	+/-
D	+	–	–	+	+/-
E	+	–	+	–	+/-

+, Positive; –, negative; +/-, positive or negative.

CPAD in the dog appears to be a complex disease with a poorly understood pathogenesis. It is still uncertain whether *C. perfringens* is a primary cause of canine diarrhea or a secondary phenomenon. In addition, much of the historical and anecdotal information regarding canine *C. perfringens* needs to be revised. Research has shed light on the several aspects of CPAD in dogs, and Table 39-9 summarizes what is known about the condition.

39.10.1.2 Pathogenesis

Knowledge about the pathogenesis of canine CPAD is limited and largely anecdotal. This phenomenon is further complicated by the fact that *C. perfringens* is a part of the normal canine intestinal microflora and readily cultured from more than 80% of diarrheic and nondiarrheic dogs.^{289,485} Canine CPAD has been attributed to CPE, which has been shown to induce fluid accumulation and diarrhea in a dog model when administered orally or directly into the intestinal lumen.³⁰ The role of CPE in the development of diarrhea is unclear because CPE is detected in up to 34% of diarrheic dogs and in 5% to 14% of nondiarrheic dogs.^{289,485} In addition, sporulated enterotoxigenic isolates are detected in up to 14% of nondiarrheic dogs.²⁸⁹ In contrast to people, in whom CPAD is usually a result of ingestion of enterotoxigenic isolates,

Infectious Diseases of the Dog and Cat, 3rd Edition

CPAD in dogs appears more likely to be secondary to disruption of the intestinal microenvironment, enabling proliferation or sporulation of commensal enterotoxigenic *C. perfringens*.

CPE is a 35-kDa protein encoded by the *cpe* gene, whose expression is coregulated with sporulation of the organism.^{72,73} Several studies have shown that the *cpe* gene can be localized on either a conjugative plasmid or on the chromosome.^{67,70,306} *C. perfringens* strains that carry a chromosomal *cpe* gene have primarily been associated with human foodborne disease, whereas strains with a plasmid *cpe* gene have been associated with human non-foodborne diseases and animal diseases, including canine diarrhea.³⁰⁶ The reason for this distinct difference is not yet fully understood. The current model of the mechanism of CPE, which has evolved primarily from the studies of McClane²⁹² and Kokai-Kun et al,²⁴⁵ is very complex and involves several steps. CPE is first produced in large quantities (15% of total protein present) by enterotoxigenic

364

365

strains during sporulation and is then released during lysis of the mother cell.^{73,292} In the foodborne model, food contaminated with large numbers of enterotoxigenic *C. perfringens* is ingested. Isolates that survive passage through the acid milieu of the stomach then undergo sporulation in the small intestine, releasing large amounts of enterotoxin.²⁹³ Non-foodborne diseases associated with CPE are thought to involve commensal enterotoxigenic strains that are somehow triggered to undergo massive sporulation. The trigger may be one of several different factors including changes in diet, antibiotic administration, or coinfection with another intestinal pathogen. Once released into the intestinal lumen, CPE interacts with specific epithelial tight junction proteins forming a small protein complex of approximately 90 kDa, where it then becomes trapped on the membrane surface.^{244,293,492} The small CPE complex then interacts with additional host proteins, forming several larger complexes, including an approximately 155-kDa complex and an approximately 200-kDa complex that contains the tight junction protein occluding.²⁹³ Studies have suggested the 155-kDa complex is responsible for the cytotoxic and histopathologic damage that provides CPE access to occludin, causing alterations in tight junction structure and function, leading to paracellular permeability changes that contribute to diarrhea.²⁹³ In the rabbit model, CPE binds to small and large intestinal epithelia, with the greatest histopathologic effect occurring in the ileum, and little or no cytotoxic effect is observed in colonic loops.^{294,295} It is unknown whether this phenomenon occurs in the canine intestine, but investigation is warranted in the face of reports of colitis being the primary clinical manifestation in canine CPAD.

Table 39-9 Summary of Clostridium perfringens—Associated Diarrhea in Dogs

- Clinical signs of CPAD are not limited to colitis.
- Fecal endospore counting is not a reliable test for establishing CPAD in the dog.
- Results of *C. perfringens* enterotoxin (CPE) immunodetection assays should be cautiously interpreted, particularly the reverse passive latex agglutination assay (RPLA), which has been shown to produce more discordant results than other immunodetection methods.
- Isolation of nonenterotoxigenic strains from a diarrheic specimen does not preclude involvement in disease because other virulence factors may be involved.
- The use of tetracyclines for management of CPAD in the dogs is discouraged.
- The optimum diagnostic approach for canine CPAD is the use of an ELISA for CPE in conjunction with PCR for detection of enterotoxigenic strains procured after a heat or alcohol shock treatment.

Infectious Diseases of the Dog and Cat, 3rd Edition

39.10.1.3 Clinical Findings

Canine *C. perfringens* has been characterized as a pathogen of the large intestine, causing clinical signs of increased pathogen of the fecal mucus, increased defecation frequency, tenesmus, and hematochezia.⁴⁵⁹ However, several studies have provided evidence that *C. perfringens* may be associated with signs of small bowel diarrhea and diffuse disease (of the small and large intestine).^{56,485} Severity of disease ranges from a mild, self-limiting diarrhea to a potentially fatal acute hemorrhagic diarrhea with severe inflammation of the intestinal mucosa.^{56,386}

39.10.1.4 Diagnosis

No gold standard exists for confirmation of canine CPAD. Historically, the diagnosis has been contingent on the simultaneous occurrence of “typical” clinical signs, the detection of large numbers of *C. perfringens* endospores in fecal smears (=3 per high-power field), and the immunodetection of CPE in fecal specimens. The authors discourage the implementation of cytologic methods and emphasize that the optimal diagnostic approach uses a combination of fecal CPE immunodetection and molecular techniques.

39.10.1.4.1 Clinical Signs

No pathognomonic clinical signs are indicative of CPAD in the dog, and the spectrum of disease attributed to the responsible organism varies greatly. As previously mentioned, CPAD can manifest with small intestinal, large intestinal, or diffuse clinical signs. CPAD should also be considered as a potential cause of acute hemorrhagic diarrhea in dogs. The authors discourage the oversimplistic characterization of CPAD by anatomic localization of clinical signs.

39.10.1.4.2 Culture

Because *C. perfringens* is a normal commensal organism of the intestinal microflora, the mere culture of an isolate from the stool is of little diagnostic significance.^{289,290,485} In addition, isolation rates for *C. perfringens* are similar in diarrheic and nondiarrheic dogs. Culture may be useful in procuring isolates for the application of molecular techniques such as PCR for detection of specific toxin genes or molecular typing of isolated strains to establish clonality in suspected outbreaks.

39.10.1.4.3 Fecal Endospores

Because sporulation is coregulated with enterotoxin production, fecal endospore counting of Wright- or Gram-stained fecal smears (=3 spores per high-power field) has been suggested as a tool for diagnosing enterotoxigenic CPAD.^{178,458} Several studies have reported no association between fecal endospore counts and the presence of diarrhea or between spore counts and the detection of CPE in fecal specimens.^{289,290,485} Furthermore, it has been demonstrated that sporulation of enterotoxigenic strains continually occurs in nondiarrheic and diarrheic dogs.²⁸⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

39.10.1.4.4 Fecal Enterotoxin Immunodetection

Detection of CPE in fecal specimens is the most widely used diagnostic tool for *C. perfringens* in humans and animals. Two commercially available immunoassays are currently used in veterinary diagnostic laboratories: a reverse passive latex agglutination assay (RPLA PET-RPLA, OXOID, Ogdensburg, N.Y.) and an ELISA (*C. perfringens* Enterotoxin Test, TECHLAB Inc., Blacksburg, Va.). Commercial veterinary diagnostic laboratories and veterinary institutions have used both assays; however, the performance characteristics for these assays have not been analyzed in the dog, and some concerns have been raised about their sensitivities and specificities. Use of the RPLA has been associated with false-positive results when compared with several different ELISA methods, thus adversely influencing the specificity of the RPLA.^{34,308} Sensitivities of immunodetection methods are extremely important considering that disease associated with CPE may depend on the concentration of CPE present within the intestinal lumen. This phenomenon is underscored by the finding that up to 14% of healthy dogs have detectable concentrations of CPE using the qualitative TECHLAB ELISA.²⁸⁹ In addition, time delays in sample processing can result in false-positive or false-negative results.²⁸⁶

39.10.1.4.5 Molecular Techniques

Analysis of fecal CPE and fecal endospore counts and isolation and PCR detection of enterotoxigenic *C. perfringens* after a heat shock treatment were performed in 32 diarrheic and 100 nondiarrheic dogs (Fig. 39-10).²⁸⁹ CPE was detected in fecal specimens via ELISA in 14% of nondiarrheic and 34% of diarrheic dogs. Although this association was significant, the fact that more than half of the ELISA-positive specimens were from nondiarrheic dogs obscures the association. However, fecal specimens from nondiarrheic dogs were far less likely to be positive for both CPE and the *cpe* gene (4%) than diarrheic dogs (28%).

39.10.1.5 Therapy

Animals with acute disease (hemorrhagic gastroenteritis) should have appropriate antimicrobial therapy, although antibiotics are commonly administered even in cases of mild or chronic diarrhea. Antibiotics that have been recommended for the treatment of canine CPAD include ampicillin, erythromycin, metronidazole, tylosin, and tetracycline (Table 39-10).^{174,458} However, evidence has shown an alarmingly high rate (21%) of in vitro resistance to tetracycline.²⁸⁷ Most isolates were susceptible to ampicillin, metronidazole, and macrolide antibiotics, although resistant strains were identified. In two dogs, recurrent diarrhea associated with metronidazole-resistant *C. perfringens* was treated with a prolonged course of oral cephalixin and dietary modification.⁴⁸³

39.10.1.6 Public Health Considerations

Injudicious antibiotic administration to diarrheic animals has likely contributed to the increased prevalence of resistance, which underscores the importance of routine susceptibility screening of bacterial pathogens. Preliminary studies have documented a high prevalence (96%) of isolates that carry a gene encoding an efflux pump for tetracyclines—the *tetA* (P) gene.²³³ Tetracycline minimum inhibitory concentrations (MICs) for these isolates ranged from 1 µg/ml to 64 µg/ml. These findings are extremely important in light of the

365

366

Infectious Diseases of the Dog and Cat, 3rd Edition

fact that tetracycline has been touted as a drug of choice for the treatment of dogs with suspected CPAD or small intestinal bacterial overgrowth, and subinhibitory concentrations have actually been recommended as a long-term therapeutic approach.^{178,458,459} Furthermore, these results raise speculation of the potential for canine commensal *C. perfringens* to serve as a reservoir capable of interspecies and intraspecies transfer of antibiotic resistance genes.^{375,402}

Fig 39-10 Percentage of nondiarrheic and diarrheic dogs positive for *C. perfringens* enterotoxin (CPE) by ELISA, *C. perfringens* culture, and enterotoxigenic *C. perfringens* by PCR. (From Marks SL, Kather EJ, Kass PH, et al. 2002. Genotypic and phenotypic characterization of *Clostridium perfringens* and *Clostridium difficile* in diarrheic and healthy dogs, *J Vet Intern Med* 16:533-540.)

a See [Appendix 8](#) for additional information on selected drugs.

b Dose per administration at specified interval.

c For chronic recurring signs, animals may be treated at the indicated dose every 12 to 24 hours.

39.10.2 *Clostridium difficile*–Associated Diarrhea

39.10.2.1 Etiology

The anaerobic, gram-positive, spore-forming bacillus *C. difficile* was first discovered in 1935 and named “*Bacillus difficilis*” because of it was so difficult to culture.¹⁸⁵ The organism was not considered a significant pathogen because it was isolated from the feces of healthy newborns. However, the organism has become recognized as one of the most common causes of human nosocomial infections since the association between *C. difficile* and antibiotic-associated colitis was made in the 1970s.^{29,235,256} The role of *C. difficile* has been extensively characterized in people and horses, in which infections vary in severity from asymptomatic (in carriers) to a potentially fatal pseudomembranous colitis in people and a reported acute necrotizing hemorrhagic enterocolitis in foals.^{227,234,235} Three toxins produced by *C. difficile* have been described: toxin A (an enterotoxin), toxin B (a cytotoxin), and *C. difficile* toxin (CDT, an ADP-ribosyltransferase). Diseases associated with *C. difficile* have primarily been attributed to the activity of toxins A and B, and strains have historically been thought to produce both toxins (toxigenic isolates) or neither toxin (nontoxigenic). More reports are being made from human clinical cases of *C. difficile*–associated diarrhea (CDAD) of variant strains isolated that produce only toxin A or toxin B.^{2,27,250} The role that *C. difficile* plays in disease in the dog is not as well documented as it is in people and horses, and most of the literature focusing on *C. difficile* in dogs is based on isolation of the organism, which ranges from 0% to 40% in apparently healthy and diarrheic dogs.^{289,369,435,485} Despite the lack of difference in isolation rates between healthy and diarrheic dogs, an association has been documented between detection of toxin A or toxin B and canine diarrhea. An outbreak of diarrhea in dogs and cats that was attributed to *C. difficile* occurred in a small animal veterinary teaching hospital.⁴⁸² Toxin A or B or both were identified in one or more fecal samples from 52% of the dogs involved.

Fecal carriage of *C. difficile* was found in 9.4% of 245 cats in a teaching hospital, and 8 (38.4%) of these cats harbored toxigenic strains.²⁸⁰ Toxigenic isolates were identified by toxin A and B gene sequences, and infected cats had risk factors of immunosuppression, concurrent disease, or antibiotic therapy. Four of the

Infectious Diseases of the Dog and Cat, 3rd Edition

cats harboring *C. difficile* had clinical signs of GI disease. No clinically healthy outpatient cats or cats from an SPF colony were found to harbor *C. difficile*. *C. difficile* was associated with diarrhea in two cats described in another report.⁴⁸⁶

C. difficile is a significant enteropathogen in human beings and horses, in which infection is most commonly associated with a disruption of the normal microflora followed by colonization with toxigenic strains. The role that *C. difficile* plays in dogs and cats is not well defined. Table 39-11 summarizes the current available information about CDAD in dogs. 366 367

39.10.2.2 Pathogenesis

In one hypothesis of the pathogenesis of *C. difficile* infection, hospitalized human patients are intermittently exposed to *C. difficile* but do not become susceptible to infection until after receiving antimicrobial therapy.²²² At that point, infection occurs, resulting in a clinically evident or subclinical colonization. If asymptomatic colonization occurs, the patient is at decreased risk of developing CDAD. Antibiotic administration, especially in hospital environments, is the most commonly reported predisposing factor for the development of CDAD in people and horses,^{31,44,235} although some reports have been made of CDAD developing in the absence of antibiotic administration.^{203,228} Although any antimicrobial can predispose an individual to CDAD, cephalosporins, penicillins, and clindamycin are most commonly incriminated. In contrast, administration of antibiotics does not appear to predispose dogs to CDAD.^{56,289,485}

39.10.2.2.1 Toxins A and B

Toxins A and B are the principal virulence factors thought to be involved in the pathogenesis of CDAD. The genes encoding these two toxins have been sequenced; together with three accessory genes, they form an approximately 19.6-kb pathogenicity locus, which is found only in toxigenic strains.¹⁸⁶ The mechanism of action for both toxins involves inactivation of Rho proteins by glucosylation, thereby causing the depolymerization of actin filaments, disruption of the cytoskeleton, cell rounding, and cell death.^{203,231} Toxin A has been shown to induce histologic damage with hemorrhagic necrosis of the mucosa as well as hemorrhagic secretion in small intestinal loops of rabbits, hamsters, and mice.^{277,304} Administration of toxin A to rabbit colonic loops produces similar histologic damage as that seen in toxin A-treated ileum but with less hemorrhage and cellular infiltration.³⁰⁴ In contrast, no tissue damage or fluid secretion is seen in toxin B-treated intestinal loops, although it is cytotoxic for in vitro cell lines.^{272,277} However, several studies suggest that toxins A and B may have a synergistic effect, with mucosal damage caused by toxin A enabling cytotoxic activity of toxin B.^{277,304} The effects of both toxins have been shown to be dose and species dependent, with certain animal species appearing to be more sensitive to the cytopathic effects of the toxins. No studies have evaluated the sensitivity of canine intestinal epithelia to either toxin A or B. In addition the effects of toxins A and B appear to be age dependent in people; high levels of toxins are detected in the feces of neonates in the absence of clinical signs of disease.^{271,472} This phenomenon may also occur in dogs. Toxigenic *C. difficile* can be isolated from up to 94% of neonatal dogs in the absence of clinical signs of disease.³⁵¹ The traditional view that pathogenic strains of *C. difficile* always produce toxins A and B is now being questioned because of additional reports of toxin A-negative, toxin B-positive strains that have been isolated from clinical *C. difficile* cases.^{2,4,250,356} No toxin variant strains have been reported in canine isolates.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 39-11 Summary of *Clostridium difficile*—Associated Diarrhea in Dogs

- CDAD is not limited to clinical signs of colitis.
- The lack of a standardized diagnostic assay makes interpretation of positive fecal toxin assays difficult. Although toxin A-negative, toxin B-positive strains have not been isolated from dogs, the potential role of these toxin-variant strains cannot be dismissed.
- The implementation of PCR for detection of toxin A or B genes in diarrheic fecal specimens combined with fecal ELISA tests for detection of toxins A and B should be used for diagnosing canine CDAD.
- Information concerning CDAD in cats is limited, although the responsible bacterium has been isolated from a higher percentage of cats with diarrhea.

39.10.2.2.2 ADP-Ribosyltransferase CDT

The *C. difficile* ADP-ribosyltransferase is a binary toxin consisting of two independently coded protein components: a binding component (CDTb) and an enzymatic component (CDTa), which catalyzes the ADP-ribosylation of monomeric actin, inducing alterations in the cytoskeleton.^{179,359} All *C. difficile* strains that harbor the CDTa and CDTb genes also contain some part of the pathogenicity locus containing the toxin A and B genes.⁴³⁶ As a result the role that CDT-producing (binary) strains play in human and equine CDADs is still unclear. The prevalence of binary-positive strains isolated from clinically affected patients has been reported to be between 6% and 13% for human strains and 24% for equine strains.^{41,348,346} CDT-positive *C. difficile* strains have not been found in any canine isolates.⁴¹

39.10.2.3 Clinical Findings

39.10.2.3.1 Dogs

Clinical signs that have been associated with canine CDAD range from asymptomatic carriage to a potentially fatal acute hemorrhagic diarrheal syndrome.^{56,289} As with *C. perfringens*, no specific anatomic localization of clinical signs seems to exist, and studies have shown that dogs with suspected CDAD commonly have signs of small and large intestinal diarrhea as well as diffuse disease characterized by concurrent involvement of the small and large intestine.^{56,289,485}

39.10.2.3.2 Cats

An acute onset of anorexia and watery diarrhea was the predominant clinical feature in six reported clinically ill infected cats.^{280,486} One cat had vomiting, fever (40.5°C [104.9°F]), and abdominal discomfort.

Infectious Diseases of the Dog and Cat, 3rd Edition

39.10.2.4 Diagnosis

39.10.2.4.1 Culture

As with *C. perfringens*, isolation of *C. difficile* from diarrheic specimens is of little diagnostic value, because isolation rates in nondiarrheic and diarrheic dogs are similar (0% to 40%).^{289,435,485} Culture may be useful for procuring strains for detection of toxin genes and typing.

39.10.2.4.2 Fecal Toxin Detection

Only a few studies evaluate the presence of toxins in diarrheic and nondiarrheic animals. In addition, no consensus has been formed among veterinary diagnostic laboratories regarding diagnosis of CDAD in the dog. The current gold standard assay is the cell culture cytotoxicity assay, which detects toxin B activity; however, this assay is expensive and requires up to 48 hours for confirmation of a negative result.²⁵⁵

Routine diagnosis of CDAD has been made based on positive fecal assays for toxins A or B.^{107,235} Currently, several commercially immunoassays are available for detection of *C. difficile* toxin A or toxins A and B in fecal specimens. Because of increasing numbers of reports of toxin A-negative, toxin B-positive strains isolated from clinical cases, the use of ELISA kits that detect both toxins is gaining preference. However, none of the commercial ELISA kits have been validated in the dog, and no standard assay is used by veterinary diagnostic labs. This is concerning given the wide range of specificities (66% to 100%) and sensitivities (33% to 95%) that have been reported for many of the kits when analyzed for human fecal toxin detection.^{5,255,329} In addition, serious concerns have been raised about the specificities of a relatively new assay (*C. DIFFICILE* TOX A/B II, TECHLAB, Blacksburg, Va.) because of a high number of toxin-positive, culture-negative results from fresh canine fecal specimens, despite cultures being processed in an anaerobic chamber.⁴⁸⁵ The TOX A/B ELISA kit used for dogs was also used in the diagnosis of *C. difficile* infection in two cats.⁴⁸⁶ This kit has not been validated for use in testing feline feces. It must be evaluated to ensure that no species-specific differences could affect the test results.⁴⁸⁶

367

368

Fig 39-11 Percentage of nondiarrheic and diarrheic dogs positive for *C. difficile* toxin A by ELISA, *C. difficile* culture, and toxigenic *C. difficile*. (From Marks SL, Kather EJ, Kass PH, et al. 2002. Genotypic and phenotypic characterization of *Clostridium perfringens* and *Clostridium difficile* in diarrheic and healthy dogs, *J Vet Intern Med* 16:533-540.)

39.10.2.4.3 Molecular Techniques

The detection rates of toxigenic *C. difficile* strains after culture is similar in diarrheic and nondiarrheic dogs (Fig. 39-11), decreasing the diagnostic value of more isolation from dogs. In addition, isolation of the organism is difficult, costly, and time consuming. Nevertheless, studies in human beings have begun bypassing culture of the organism and directly determining the presence of specific toxin genes in DNA obtained from fecal specimens. Sensitivities of PCR detection methods used in people have been reported to be between 96% and 100%, compared with the less effective cytotoxicity assay.^{180,496} Although most commercial veterinary diagnostic laboratories do not currently offer PCR as a diagnostic test for CDAD, these techniques may be beneficial, especially considering the potential false-positive ELISA results for

Infectious Diseases of the Dog and Cat, 3rd Edition

detection of toxins A or B. In cats with *C. difficile* infections, PCR was used to detect gene sequences for toxin A and B. In addition, DNA analysis has been used to classify individual isolates.

39.10.2.5 Therapy

Metronidazole is the drug of choice for treatment of dogs suspected to have CDAD. Although metronidazole-resistant *C. difficile* isolates obtained from foals and adult horses have been reported, a study evaluating the in vitro susceptibilities of 70 canine *C. difficile* isolates did not demonstrate any evidence of resistance to metronidazole.²⁸⁷ The second drug of choice for humans and occasionally horses is vancomycin; however, it is used only in cases of unresponsive CDAD or when metronidazole-resistant strains have been found. In a study of 70 fecal isolates from dogs, all isolates had MICs of 1 µg/ml for metronidazole and vancomycin.²⁸⁷ Diarrheic cats harboring toxigenic strains of *C. difficile* have responded to metronidazole treatment.^{280,486}

39.10.2.6 Prevention

Should CDAD be identified, infection control measures should be implemented to restrict contamination through the environment. Affected animals must be quarantined and barrier precautions must be taken (e.g., wearing gowns, gloves, and overboots) by personnel when handling these animals. Housing areas should be decontaminated with dilute (10%) bleach, and disinfectant footbaths should be placed at the entrance to these areas. Common exercise areas are considered a potential source of contamination.

39.10.2.7 Public Health Considerations

Although animal reservoirs of *C. difficile* infection exist for humans, the incidence of community-acquired CDAD in people is low. In contrast, nosocomial infection in hospitalized humans receiving antimicrobial therapy is high.²²² Pseudomembranous colitis, now known to be caused by *C. difficile*, is a toxin-mediated infection that is predisposed by immunosuppression or an imbalance in the intestinal microflora.

40 CHAPTER 40 Canine Brucellosis

Craig E. Greene

Leland E. Carmichael

40.1 ETIOLOGY AND EPIDEMIOLOGY

Brucella canis is a small (1.0 to 1.5 μm), gram-negative, aerobic, coccobacillary organism. Its rough colonial morphology and differences in biochemical and antigenic reactions distinguish it from other members of the genus *Brucella*. Unlike the smooth *Brucella* organisms that infect several domestic animal species, *B. canis* has a limited host range; only dogs and wild *Canidae* have been found to be susceptible. Cats can be infected experimentally, having a transient bacteremia, but are relatively resistant. Rabbits and nonhuman primates also have been found to be susceptible to experimental infections. No other animal species has developed significant agglutination titers. Human cases have been reported as a result of laboratory accidents and contact with infected dogs, but people appear to be relatively resistant (see Public Health Considerations).

The *Brucella* genus is composed of six classical species based primarily on host preference: *Brucella abortus* (cattle), *Brucella canis* (dogs), *Brucella melitensis* (goats, sheep), *Brucella neotomae* (rodents), *Brucella ovis* (sheep), and *Brucella suis* and its biovars (pigs, cattle, hares, rodents, and wild ungulates). Novel *Brucella* (*Brucella maris*) have been isolated from cetaceans and pinnepeds¹⁴; however, the isolates appear to uniquely infect marine mammals. Dogs also are susceptible to infection with *B. abortus*^{7,29,67} and *B. suis*.¹¹ Even attenuated vaccine strains of *B. abortus* can infect dogs.⁶¹ Natural infection is thought to occur after ingestion of contaminated placentas and aborted fetuses from livestock. Dogs usually harbor the organisms in the lymph nodes of the gastrointestinal tract for extended periods. Dogs are not believed to be important in the spread and maintenance of these infections. Testing and removal of affected dogs from infected farms are the optimal preventive measures for eradication.

B. canis infects a susceptible host by penetrating the mucous membranes, especially those of the oral cavity, vagina, and conjunctiva. The minimum oral infectious dose for dogs is approximately 10^6 bacteria, and the conjunctival dose is 10^4 to 10^5 organisms. Because they contain the highest concentration of organisms, vaginal discharges and semen are the most likely sources for infection by mucosal contamination.

Natural transmission of canine brucellosis occurs by several routes. Infected female dogs transmit *B. canis* during estrus, at breeding, or after abortion through oronasal contact with vaginal discharges. Transmission is most common by oronasal contact with aborted materials because they contain up to 10^{10} organisms/ml. Shedding of *B. canis* may occur for periods up to 6 weeks after an abortion. Milk of infected bitches contains lower concentrations of organisms and appears to be less important in transmitting infection to surviving pups; most have already been infected in utero or congenitally.

Seminal fluid and urine have been incriminated as sources of infection from male dogs that harbor the organisms in their prostates and epididymides. The rate of isolation of *B. canis* from the semen of infected dogs is usually high for the first 6 to 8 weeks postinoculation (PI). Intermittent shedding of the organism in low numbers has been noted for up to 60 weeks PI and may continue for at least 2 years. Urinary excretion begins a few weeks after the onset of bacteremia and continues for at least 3 months. Concentrations of 10^3 to 10^6 organisms/ml of urine have been found in male dogs, with lesser numbers of bacteria in the urine of females. At one time, urine of infected

Infectious Diseases of the Dog and Cat, 3rd Edition

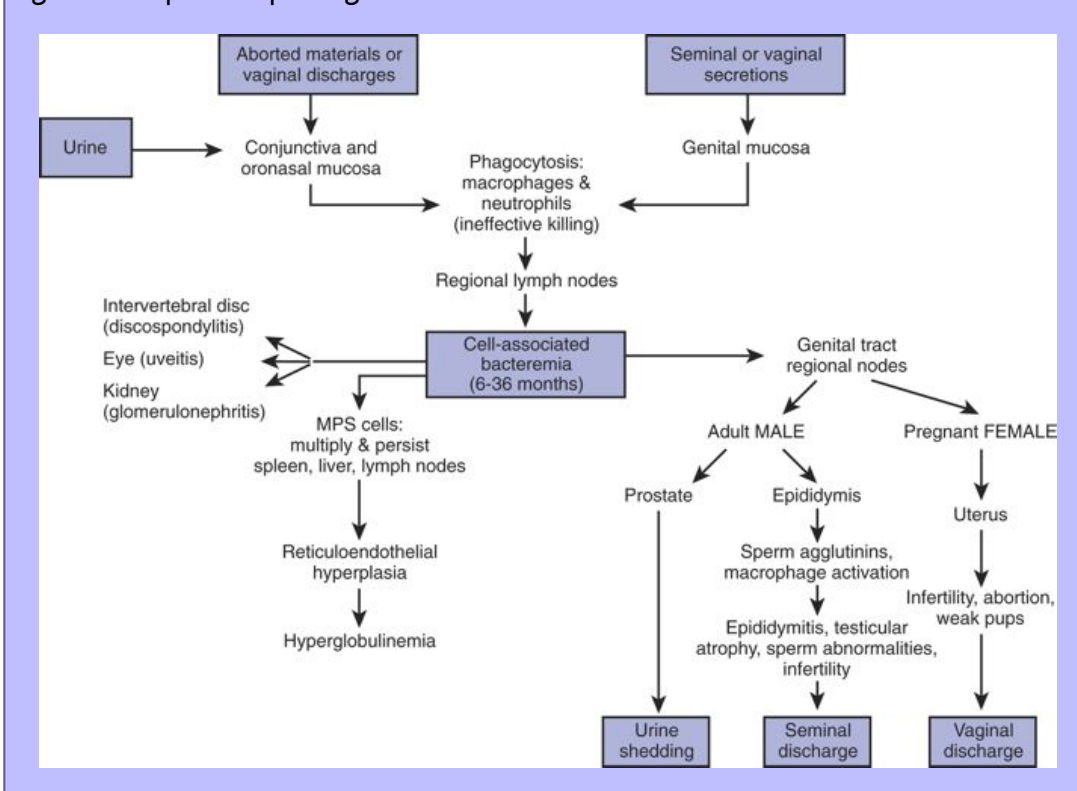

males was thought to contain too few organisms to be infectious by the oronasal route; however, studies have demonstrated that *B. canis* can be transmitted from infected to uninfected mature male dogs after several weeks or months of close contact.^{18,69} The propensity of males to shed the organism in the urine is probably related to its localization in the prostate and epididymis, which are in close association with the urinary bladder. Neutering helps reduce this risk to a large extent.

Alternative means of transmission occur less frequently under natural circumstances. Transmission via fomites has been reported after vaginoscopy, blood transfusion, artificial insemination, and use of contaminated syringes. *B. canis* is relatively short lived outside the dog and is readily inactivated by common disinfectants.

The prevalence of infection varies according to the animal's age, housing conditions, breed, and geographic location. Pet dogs in suburban environments have a lower prevalence compared with stray dogs in economically depressed areas, which may reflect increased population density and uncontrolled breeding of dogs. A relatively low prevalence has been reported in the United States and Japan (range, 1% to 18%) compared with rates as high as 28% in Mexico and Peru.¹⁵ The southern United States appears to have a relatively higher (approximately 8%) prevalence of infection. Among breeds in this region, beagles and Labrador retrievers have a higher prevalence of infection as do feral dogs. Determination of seroprevalence is strongly influenced by the means of testing and interpretation. Cases have also been identified in other countries in Central and South America and in Germany, Spain, Czechoslovakia, and Tunisia.²⁰ The disease also appears to be prevalent in regions of the People's Republic of China.³⁶ Given the insidious nature of *B. canis* in dogs, isolated infections have been found in imported dogs, even in countries such as the United Kingdom, where quarantine standards are very stringent.²⁶

370

Fig 40-1 Sequential pathogenesis of canine brucellosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

40.2 PATHOGENESIS

The general sequence of events after infection by *Brucella* is summarized in Fig. 40-1. The bacteria are probably phagocytized at contaminated mucosal sites by tissue macrophages and other phagocytic cells and transported to lymphatic and genital tract tissues where they multiply. They persist intracellularly within mononuclear phagocytes.⁶⁴ Brucellae evade phago-lysosome fusion and replicate in a compartment within the cell's endoplasmic reticulum.²⁵ A leukocyte-associated bacteremia occurs beginning 1 to 4 weeks PI and can last 6 to 64 months. Generalized lymphoreticular hyperplasia (Fig. 40-2) and development of hyperglobulinemia occur during the course of infection. As with other intracellular parasites, cell-mediated immunity is probably the most important defense mechanism against *B. canis*. Studies in people have indicated decreased T-lymphocyte responsiveness to *Brucella* cytoplasmic proteins in more chronic infections.³² Persistent nonprotective antibody titers are characteristic of such infections and appear to have little influence on the level of bacteremia or number of organisms in tissues. The greatest numbers of *B. canis* organisms are found in the lymph nodes, spleen, and tissues of gonadal steroid dependency. Although usually confined to mononuclear phagocytes, they may enter other cells such as placental epithelium. In fact, the uterus is not a favored site of growth in the nongravid or diestral female. Inflammation of the epididymides and testes in males causes sperm leakage, which provokes the immune system to produce a complex of antisperm agglutinating antibodies and delayed-type hypersensitivity reactions against sperm that are unrelated to the antibodies against *B. canis*. The immune responses produced against spermatozoa contribute to the epididymitis, infertility, and eventual spermatogenic arrest seen in most infected male dogs.

Fig 40-2 Follicular hyperplasia in the lymph node from a dog with chronic *B. canis* infection (H and E stain, × 40).

B. canis, similar to other blood-borne bacteria, may localize in nonreproductive tissues such as the endarterial circulation of the intervertebral disk, causing diskospondylitis. Other tissues that filter blood-borne organisms or

370

Infectious Diseases of the Dog and Cat, 3rd Edition

immune complexes may become involved, including the eye (anterior uveitis), kidney (glomerulopathy), and meninges (meningoencephalitis).

371

Spontaneous recovery from infection may occur within 1 to more than 5 years PI. Therapy accelerates the recovery process. Some dogs may have persistent bacteremia throughout this time, whereas others can harbor bacteria in tissues for several months after the bacteremia ceases. The prostate gland may be a site of this persistence in male dogs. Despite tissue persistence, when *B. canis* is no longer detected in the blood, serum agglutination titers decrease.

Dogs that recover naturally have low or negative agglutination titers and yet are immune to reinfection, suggesting that protective immunity is cell mediated. Recovered dogs that were challenged orally or intravenously as long as 4 years after spontaneous recovery from experimental infection were completely immune.⁵⁵ However, chronically infected dogs that were successfully treated with antibiotics were found to be fully susceptible to oronasal challenge 12 weeks after treatment had been halted. Natural recovery from *B. canis* infection appears to be a requirement to sustain protective immunity. Immunosuppression with glucocorticoids and antilymphocyte serum appears to increase the susceptibility of dogs to initial infection, but it does not augment the severity of the disease or alter the course of infection in experimentally infected dogs.

40.3 CLINICAL FINDINGS

Despite generalized systemic infection with *B. canis*, adult dogs rarely are seriously ill. Fever is uncommon and, with the exception of males who commonly have epididymitis, most infections will not be diagnosed by routine history or physical examination. Owners of working dogs have occasionally reported dry, lusterless coats, loss of vigor, and decreased exercise tolerance. Nongravid females show no signs of illness other than lymphadenomegaly, which occurs in both sexes.

Overt clinical signs usually involve reproductive disturbances in sexually mature animals. Bitches usually abort dead pups between 45 and 60 days of gestation but show no other clinical signs. Pups are usually partially autolyzed, with subcutaneous edema and congestion and hemorrhage of the abdominal subcutaneous region (Fig. 40-3). Moderate quantities of serosanguineous peritoneal effusions are found. Their appearance suggests fetal death in utero some time before abortion. Decomposed fetuses are not usually found because the bitch ingests them. Abortion is characterized by a brown or greenish-gray vaginal discharge that lasts for 1 to 6 weeks. Brucellosis should be suspected under any circumstance when apparently healthy bitches abort 2 weeks before term.

Although abortion of dead puppies is the primary clinical sign reported with brucellosis, conception failures could occur at any time after breeding. In utero death with fetal resorption or abortion and ingestion of fetuses may be suspected if a bitch fails to conceive after an apparently successful mating. Embryonic death may occur as early as 20 days after mating, although most conception failures are actually undetected abortions. Less commonly, bitches may carry infected puppies to term and whelp both live and dead puppies within a single litter. Most pups that are born alive will die within a few hours or days, but those that survive or that are infected as neonates usually have generalized peripheral lymphadenomegaly as the primary clinical manifestation of disease until they reach sexual maturity. Such puppies usually have persistent hyperglobulinemia (Fig. 40-4), and some may have transient fever, leukocytosis, or seizures as the systemic manifestations of their infections.

As with brucellosis in other species, infections with *B. canis* do not interfere with normal estrous cycles. A high proportion of bitches that abort may have normal litters subsequently. However, even after having normal litters, some infected bitches experience intermittent reproductive failures.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 40-3 Partially autolyzed fetuses with placenta and uterus from a dog infected with *B. canis* that was neutered at 45 days gestation. (Courtesy University of Georgia, Athens, Ga.)

Because of the prominent testicular abnormalities, male dogs are presented for examination more often than are females, even though impairment of male reproductive performance often is less noticed. Nevertheless, infertility occurs. Males appear to be in good health but may have an enlarged scrotum because of accumulation of serosanguineous fluid in the tunica. Scrotal dermatitis is the result of constant licking and secondary infection with nonhemolytic staphylococci (Fig. 40-5). A major cause of testicular swelling is enlargement of the tail of the epididymis (Fig. 40-6); orchitis and primary testicular enlargement are rarely apparent. In fact, chronically infected males usually develop unilateral or bilateral testicular atrophy. A decreased volume of ejaculate without loss of libido is usually present. Acute pain is not usually evident on scrotal or testicular palpation, but discomfort may be seen at the time of ejaculation.

Nonreproductive abnormalities can also occur. Splenomegaly may accompany the diffuse lymphadenomegaly in some dogs. Dogs with diskospondylitis initially experience spinal pain and later paresis and ataxia if spinal cord compression develops (Fig. 40-7). Osteomyelitis or polyarthritis of the appendicular skeleton causes lameness of

Infectious Diseases of the Dog and Cat, 3rd Edition

the affected limb. Meningoencephalitis has been reported after experimental and natural infections; however, neurobrucellosis in dogs, as in people, is uncommon.⁵³ The author has observed that a male dog with confirmed *B. canis* infection had behavioral changes, anisocoria, ataxia, hyperesthesia, head tilt, and circling. Neurologic signs began within 3 weeks after the dog's first breeding. Chronic multifocal pyogranulomatous dermatitis that resembled lick granuloma lesions has also been reported in an infected dog, but a direct causal relationship was not established. Ocular lesions include anterior uveitis, secondary glaucoma, hyphema, retinal detachment, chorioretinitis, optic neuritis vitreal haze, enophthalmitis with secondary glaucoma or phthisis bulbi, and corneal edema with opacification (Fig. 40-8).⁷⁶ The author has observed residual chorioretinal lesions following treatment of dogs with uveitis. See Chapter 93 for a review of ocular brucellosis.

40.4 DIAGNOSIS

40.4.1 Clinical Laboratory Findings

Hematologic and biochemical values are either unaltered or nonspecific in canine brucellosis.

372

Hyperglobulinemia (β and γ) with concomitant hypoalbuminemia has been the most consistent finding in chronically infected dogs. An increased incidence of positive Coombs' test findings in the absence of anemia has been reported. Examination of aspirates or biopsy samples from enlarged lymph nodes usually reveals lymphoid hyperplasia with large numbers of plasma cells. Cerebrospinal fluid analysis results are pleocytosis, primarily consisting of neutrophils, and increased protein concentration with meningoencephalitis, but they are unremarkable when diskospondylitis alone is present. Urinalysis is usually normal despite the variable presence of bacteriuria. Radiographic demonstration of intervertebral disk infection should always be followed by

373

Infectious Diseases of the Dog and Cat, 3rd Edition

serologic testing and, when possible, bacteriologic confirmation of *B. canis*. Radiographic changes of diskospondylitis may be difficult to visualize in the first weeks of infection because brucellar spondylitis is a slow process. Brucellar diskospondylitis can be unifocal or multifocal. The infection centers on the disk space; vertebral architecture is usually preserved, and minimal adjacent spinal soft-tissue involvement is typical. Radionuclide scintigraphy is a sensitive way of detecting inflammatory alterations in the bone, and additional imaging modalities such as computed tomography or magnetic resonance imaging may also be helpful.

Fig 40-8 **A**, Uveitis and healed **(B)** chorioretinal lesions (*arrows*) from a dog with brucellosis. (Courtesy Leland Carmichael, Cornell University, Ithaca, N.Y. **[A]** and University of Georgia, Athens Ga **[B]**.)

40.4.2 Semen Examination

Semen abnormalities, evident by 5 weeks PI, become pronounced by 8 weeks PI. Abnormalities include immature sperm, deformed acrosomes, swollen midpieces, and retained protoplasmic droplets. By week 15 PI, bent tails, detached heads, and head-to-head agglutination is seen. Large aggregates of inflammatory cells, usually consisting of neutrophils, surround adherent macrophages containing phagocytized sperm (Fig. 40-9). More than 90% of the sperm are abnormal by 20 weeks PI. Aspermia without inflammatory cells corresponds with the development of bilateral testicular atrophy. Semen morphology should always be evaluated in dogs with infertility because of the obvious abnormalities that occur with brucellosis.

40.4.3 Serologic Testing

Serologic testing is the most frequently used diagnostic method for detecting canine brucellosis. These tests are subject to considerable interpretive error because lipopolysaccharide (LPS) antigens of several bacterial species cross-react with *B. canis*.^{49,51} The problem of false-positive cross-reactions therefore is more common than that of false-negative reactions. All sera should be free of hemolysis because hemoglobin causes false-positive agglutination of the tube test antigen.

Fig 40-9 Stained smear of semen sample from a dog 35 weeks PI. Sperm abnormalities are present. (Courtesy Leland Carmichael, Cornell University, Ithaca, N.Y.)

Serologic test results often are negative during the first 3 to 4 weeks PI despite the presence of bacteremia by 2 weeks PI. For this reason, newly acquired animals should be tested sequentially at least twice at 30-day intervals before introduction into a breeding kennel. Titers by any method are usually positive by 8 to 12 weeks after infection. Low or intermediate titers may mean previous disease or very recent infection, and testing should be repeated or attempts made to isolate the organism by hemoculture. Male dogs may harbor the organism in the prostate glands and epididymides for extended periods after bacteremia ceases and agglutination titers have declined. Serologic titers may remain positive for up to 36 months in some dogs after they become abacteremic.

373

374

Chronically infected female dogs may have diagnostically equivocal antibody titers and negative blood cultures. In females, recrudescence of bacteremia and increased antibody titers develop during proestrus, estrus, pregnancy, or abortion. These times are the most reliable to screen female dogs for infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 40-1 Comparison of Serologic Procedures for Canine Brucellosis

SEROLOGIC TEST	ANTIGEN USED	EARLIEST TITER ^a (WEEKS PI)	ADVANTAGES	DISADVANTAGES
Antibody Detection Methods				
Mercaptoethanol (ME) rapid slide agglutination test (ME-RSAT)	Cell wall	3–4	Quick, high sensitivity, few (1%) false-negative results	False-positive results common; must confirm by other tests
Tube agglutination test (TAT)	Cell wall	3–6	Semiquantitative determination	False-positive results similar to RSAT
ME-TAT	Cell wall	5–8	Same as TAT, somewhat increased specificity	Longer to get positive titer compared with TAT
Agar-gel immunodiffusion (AGID) cell wall (somatic) antigen	Cell wall (LPS)	5–10	Very sensitive, positive earlier than with CPAg	Procedure and interpretation complex, nonspecific reactions
Internal cytoplasmic protein antigen (CPAg)-AGID	CPAg	8–12	Most specific (confirmatory) test, detects chronic cases when other tests have negative results; detects infections by other <i>Brucella</i> species	Complex procedure, least sensitive for initial screening, variable duration of time with positive result; may stay positive for up to 1 year after recovery from infection
Indirect FA	Cell wall (LPS)	Unknown	Available and convenient for diagnostic laboratories	May be less sensitive than ME-TAT as screening test; not extensively evaluated
ELISA	Cell wall (LPS) or CPAg	Unknown	Good results with mutant (M-) <i>B. canis</i> for cell wall extracts, or <i>B. abortus</i> for CPAg	Antigen purity and preparation critical
Organism Detection Methods				
Blood culture	Not applicable	2–4	A positive result is confirmed infection	False-negative results possible
PCR	Not applicable	2–4	Rapid results, a positive result indicates infection if specific primers are used and contamination is excluded	False-positive results possible with contamination and false-negative results with inadequate extraction methods

FA, Fluorescent antibody; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

^a First significant titer to appear. Data based on adult dog.

Antibiotic therapy may suppress bacteremia and the associated serologic response, possibly contributing to false-negative serology and failure to isolate the organism from infected dogs. Antibacterials should not be given until diagnostic tests have been completed. Tetracycline drugs cause a bacteremia and a corresponding decrease in antibody titer that may rebound after treatment is discontinued because tetracyclines are not bacteriocidal.

374

Fig 40-10 Diagnostic algorithm for canine brucellosis. The indirect FA and ELISA tests are being used more as screening tests because of unavailability of ME-RSAT and ME-TAT test antigens (see text). Titer is equal to numeral of the dilution ratio following the colon.

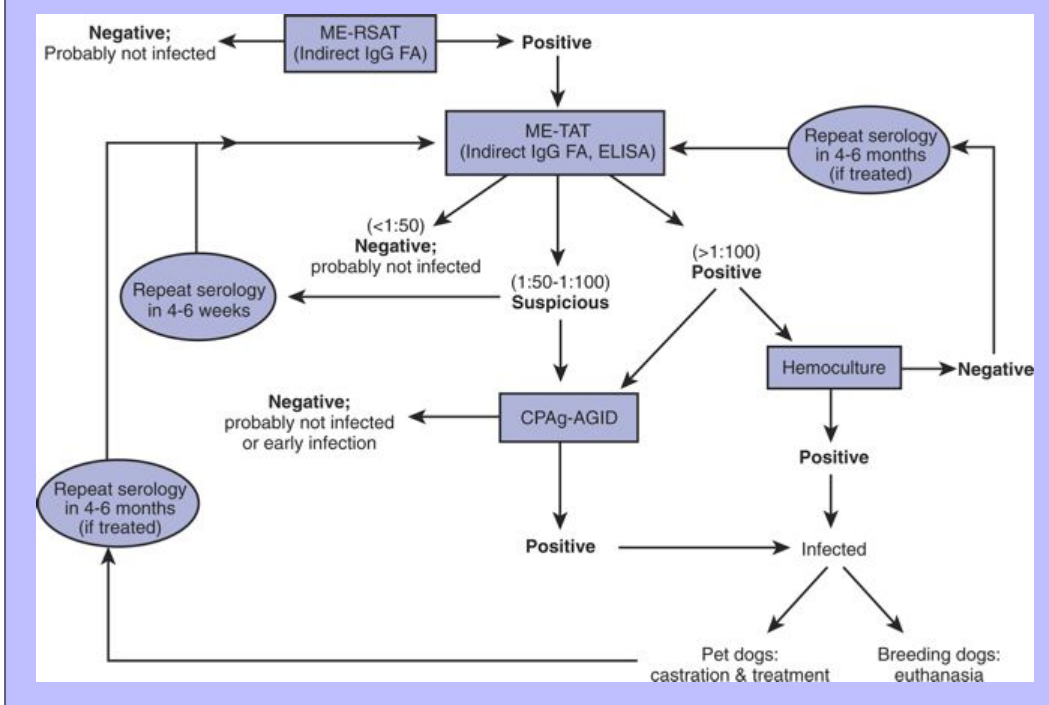

Table 40-1 compares the serologic tests described next. Consult Appendices 5 and 6 for information concerning commercially available testing. Serologic tests should be evaluated in light of clinical findings in the dog being evaluated (Fig. 40-10). A single high agglutination titer to *B. canis* usually indicates active infection, but this should be substantiated by additional tests. Dogs that are asymptomatic but have positive results on agglutination procedures should never be condemned as infected until blood culture results or the more specific cytoplasmic protein antigen (CPAg)–agar gel immunodiffusion (AGID) test results confirm the positive findings. All tests, with the exception of the CPAg-AGID method, measure antibodies to LPS antigens and may give nonspecific test results.

40.4.3.1 Rapid Slide Agglutination Test

The 2-mercaptoethanol rapid slide agglutination test (ME-RSAT) is preferred as an in-office screening procedure because it is inexpensive, rapid, and sensitive; it also detects antibodies early (D-Tec CB, Synbiotics, San Diego, Calif.). A 99% correlation exists between a negative test and lack of infection. The test kit used rose Bengal–stained *B. ovis* because its growth is less mucoid than *B. canis*. *B. canis* cross-reacts with all rough *Brucella* and with certain other bacterial species, such as mucoid strains of *Pseudomonas*, *Bordetella bronchiseptica*, and *Actinobacillus equuli*, to which serum antibodies may be present. Most causes of cross-reactions, however, have not been identified. Some breeds (e.g., Irish wolfhounds and Old

Infectious Diseases of the Dog and Cat, 3rd Edition

English sheepdogs) have an exceptionally high false-positive test result rate for unknown reasons.²⁰ The ME-RSAT substantially reduces false-positive reactions by eliminating less specifically reacting IgM antibodies. 2-mercaptoethanol (ME) is labile and must be kept in a dark, tightly stoppered bottle at 4°C; use of inactivated ME gives false-positive results. A modification of the RSAT, using a less mucoid variant of *B. canis*, further reduces the rate of false-positive results.^{49,51} The ME-RSAT with the *B. canis* M-antigen therefore can be employed for confirmation of positive results of screening tests.

40.4.3.2 Tube Agglutination Test

The tube agglutination test (TAT) has been the most widely used serodiagnostic procedure for confirmation of infection in ME-RSAT-positive dogs. However, availability of antigen formerly provided by the U.S. Department of Agriculture is erratic. As with the RSAT, the TAT is also troubled by heterospecific reactions with other infectious agents and by equivocal titers in chronically infected animals; therefore the ME modification is used. Unfortunately, the ME-TAT also shows a lack of specificity, and the increase in ME-TAT antibody titers usually lags 1 to 2 weeks behind those of the TAT and 2 to 4 weeks behind those of the ME-RSAT. Nevertheless, results of the ME-RSAT correlate well with the ME-TAT, both of which should be considered as screening tests.

Lack of standardized reagents or methods makes absolute ME-TAT titer comparisons difficult. Nevertheless, a titer of 1:50 may indicate either very early (less than 3 weeks) or recovering infections. Titers of 1:50 to 1:100 should be considered suspect for infection; and titers of 1:200 or greater are highly presumptive of active infection because they often correlate with positive hemocultures. However, sera from noninfected dogs have been found to have titers from 1:50 to 1:100 and occasionally higher. As a semiquantitative test, the ME-TAT is best in control programs to quantitate serologic responses of dogs over months to determine whether infection has been eliminated with chemotherapy (see Therapy).

40.4.3.3 Agar Gel Immunodiffusion Test

This test, using selected antigens, has been developed as both a sensitive and specific procedure for the serodiagnosis of canine brucellosis. With regard to sensitivity, AGID tests reveal precipitins in the sera of infected dogs only after 5 to 10 weeks PI; however, antibodies persist for several weeks or months after the bacteremia has ceased. The AGID test, using cell wall (somatic) LPS antigen, has the same problems of cross-reactions as do agglutination tests, but positive sera may be distinguished from false-positive sera by a distinct precipitin band for *B. canis* (Fig. 40-11, A). The somatic LPS antigen is seldom employed in the diagnostic regimen because of the lack of standardization and difficulty of interpreting test results.

375

376

Fig 40-11 **A**, AGID patterns using sodium desoxycholate (SDC)-extracted somatic (LPS) antigens reacted with positive (P) and false-positive (FP) sera. Cross-reactions are evident. Arrows indicate *B. canis*-specific precipitin line. **B**, Cytoplasmic protein antigen (CPA). Precipitin lines occur only with sera from *Brucella*-infected dogs using CPA.

The CPAG-AGID test, which is highly specific for *Brucella*, uses internal cytoplasmic antigens liberated by sonication of *B. canis* (see Fig. 40-11, B) or *B. abortus*.⁹ Cytoplasmic antigens are shared only among *Brucella* organisms and will not react with antibodies to other genera of bacteria as seen with agglutination testing. The CPAG test has been able specifically to detect precipitins in the sera from dogs after other tests have become equivocal or even negative. It should be used as a confirmatory test following other serologic methods. A high proportion of sera sent to a reference laboratory for CPAG-AGID testing that are positive or suspect in the commercial ME-RSAT or the ME-TAT are found to be false-positive reactions.²⁰

A disadvantage of tests with CPAG is the longer period between infection and the presence of detectable precipitins¹⁹ (see Table 40-1). Furthermore, one or more precipitin lines may persist up to 12 months after bacteremia has ceased. In contrast to LPS antigens, both rough and smooth *Brucella* share the internal protein antigens. Thus the possibility of infection with other *Brucella* (e.g., *B. suis* or *B. abortus*) must be considered when CPAG is used. False-positive reactions have not been observed with non-*Brucella* species. False-negative results can occur in some dogs, presumably with early infections, whose sera are RSAT positive and AGID negative. Hemoculture is the only definitive way to resolve these differences.

Infectious Diseases of the Dog and Cat, 3rd Edition

40.4.3.4 Indirect Fluorescent Antibody Testing

As a result of a production shortage in the RSAT test kit and the unavailability of TAT reagents, many diagnostic laboratories have switched to the indirect fluorescent antibody (FA) test or enzyme-linked immunosorbent assay (ELISA) for serologic screening. Although these tests are being widely performed, they have not been as consistently evaluated as have the ME-RSAT, ME-TAT, and AGID methods. The indirect FA allows for visualization of the organism in the test procedure, and potential use of IgG-specific conjugates; however, nonspecific reactions still occur. With any test the purity and specificity of the antigen and homogeneity of the antibody conjugate are critical. The sensitivity of the indirect FA method is uncertain but may be lower than that of the ME-TAT and ELISA, meaning that some infected dogs may be missed during screening.

40.4.3.5 Enzyme-Linked Immunosorbent Assay

Newer methods for detection of *Brucella* infection have involved the use of ELISA.⁴⁶ As with other assays, the antigen source is critical in establishing test specificity. An antigen-specific, sandwich ELISA using highly purified *B. canis* cell wall antigen has been developed as a serologic test for *B. canis* infection.⁷⁰ Though very specific, ELISA may be less sensitive than the TAT in screening for infected dogs. Cytoplasmic *Brucella* protein (CP) extracts or lumazine synthase (LS) treatment of *B. abortus* proteins have also been used^{9,10} in an attempt to improve ELISA test accuracy.¹⁰ Recombinant ribosome recycling factor from *Brucella melitensis* has also been used to test human and canine sera.²² The sensitivity of the ELISA has also been improved by a hot saline (HS) extract of the M-variant strain of *B. canis*.⁵² HS, CP, or LS protein-based ELISAs were 97%, 94%, and 88% sensitive and 94.3%, 96.7%, and 96.7%, specific, respectively, in detecting dogs with confirmed or suspected brucellosis.⁷⁸ ELISA results usually were positive within 30 days after infection.⁷⁸ ELISAs have also been developed using recombinant produced proteins of *Brucella*.⁵ Because of their convenience, ELISA methods may be further evaluated as screening tests and for quantitating serologic responses in naturally and experimentally infected dogs.^{9,48}

40.4.4 Bacterial Isolation

Isolation of *B. canis* is time consuming but not difficult because the organism grows well aerobically on conventional media used for other *Brucella*. Of the *Brucella* infecting dogs or people, *B. canis* is the only one with a consistent *mucoïd* (rough) colonial morphology because its cell wall contains truncated LPS moieties. However, less common rough strains of the other species develop, especially after culture on artificial media.

376

377

Blood is the most practical tissue or fluid for isolating the organism. Isolation of the organism from blood is the most definitive diagnostic procedure. Hemoculture should not be the sole criterion for infection because the bacteremia, although generally sustained, may be absent or intermittent in more chronically infected animals. Antibiotic administration may interfere with successful isolation of the organism. Blood culture can be helpful if serologic tests are ambiguous. Whole blood must be taken for culture because the organisms are associated with the leukocyte fraction. Bacteremia is detected 2 to 4 weeks after oronasal infection and, if untreated, persists for long (1 to 2 years or more) periods. Experimentally infected dogs have remained blood-culture positive for as long as 5.5 years. Bacterial numbers in the blood exceed 10^3 /ml after 4 to 5 weeks PI and remain high for many (generally at least 6) months.²¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Urine culture is positive in some dogs, especially males, when blood cultures are negative; however, unless cystocentesis is performed, urinary isolation of *B. canis* may be difficult because of overgrowth by urethral contaminants. However, urine collected via the urethra may have greater levels of semen, which is a predominant source of *B. canis* organisms. Collection of semen by ejaculation is valuable for culture during the first 3 months of infection, when the concentration of organisms is greatest. With diskospondylitis, culture of disk or bone specimens removed at surgery, or material from needle aspiration of the disk space, may also be cultured.

B. canis can be isolated at necropsy from several tissues of hemoculture-positive dogs. The lymph nodes, spleen, liver, bone marrow, and male reproductive organs are the most common sources, even though gross lesions are seldom present. In females, the gravid or estrual uterus, the placenta, and vaginal or uterine fluids are most consistent tissues for isolation.

40.4.5 Laboratory Cultivation

Contamination of specimens for culture of *B. canis* should be avoided because of overgrowth by faster-growing bacteria. Antibiotics such as bacitracin, polymyxin, and cycloheximide are usually added to the media before cultivation. Whole blood or fluid samples are usually cultured for 4 to 5 days at 37°C in Albimi, Trypticase soy, or Tryptose broth (Difco Labs, Detroit, Mich.), with citrate added as an anticoagulant. After 4 to 7 days of growth, cultures are streaked on solid media such as *Brucella* broth (BBL, Cockeysville, Md.), Tryptose agar, horse or cow blood agar, Trypticase soy agar (BBL, Cockeysville, Md.), or Thayer-Martin media (Difco Labs, Detroit, Mich.). Automated culture systems (Bact/Alert System, Organon Teknica, Durham, N.H.) have been helpful in giving consistent isolation times between 48 to 72 hours from the time of whole blood sample submission.⁶⁵ Tissue swabs or specimens may be streaked directly onto solid media and incubated aerobically at 37°C. Growth is not usually seen before 48 hours. Initially, colonies appear small and translucent but become mucoid after several days of incubation. Biochemical and immunologic methods and phage typing help identify isolates of *B. canis*.

40.4.6 Genetic Detection

Polymerase chain reaction (PCR) has also been used to detect *Brucella* species in tissues and fluids.¹³ A genus-specific PCR, based on the gene encoding BCSP31, an antigenic periplasmic protein, is conserved in all species.^{8,24,13} PCR has been more sensitive than blood culture and serology in detecting infection in human patients.⁵⁶ Using this method, at least two biovars of *B. canis* have been identified.⁴³ Molecular characterization of isolates has been helpful for differentiating among *Brucella* in the clinical laboratory.³⁰ That the conserved 16S rRNA sequences of *Brucella* species of domestic animals are over 98% similar indicates these organisms are closely related to *Bartonella* and *Agrobacterium*. The interspace region of this gene is unique for *Brucella* and is useful in differentiating them from other isolated bacteria.

40.5 PATHOLOGIC FINDINGS

Macroscopic changes in adults or surviving pups are usually confined to lymphadenomegaly and splenomegaly. Histologic changes are relatively uniform. Lymph node enlargement is the result of diffuse lymphoreticular hyperplasia (Fig. 40-12). In dogs with chronic bacteremia, lymph node sinusoids and the spleen are filled with plasma cells and macrophages containing phagocytized bacteria. Special stains (e.g., Brown-Brenn stain) must be used to detect intracellular organisms.

Infectious Diseases of the Dog and Cat, 3rd Edition

Diffuse submucosal lymphocytic infiltration occurs in all genitourinary organs. A necrotizing vasculitis occurs in the target tissues of gonadal steroids, including the prostate, scrotum, sheath, or vulva. Lesions are most prominent in the prostate, epididymis, and uterus, whereas milder changes are observed in the renal pelvis, testes, ductus deferens, urinary bladder, and ureters. Extensive necrosis of the prostatic parenchyma and seminiferous tubules is caused by inflammatory cell infiltration, which eventually results in atrophy or fibrosis (Fig. 40-13). A chronic to subacute endometritis can be seen in the uterus, with glandular hyperplasia and reticular cell nodules (Fig. 40-14). Focal hepatic necrosis, myocarditis, and meningoencephalitis also have been described. Renal abnormalities occur in some dogs and consist of hyaline thickening of the basement membrane of glomeruli with minimal cellular infiltration or proliferation. A mild interstitial nephritis has been noted. Ocular disease includes granulomatous iridocyclitis and exudative retinitis, consisting of diffuse infiltration of lymphocytes, plasmacytes, and neutrophils. Corneal endothelium has vacuolated cytoplasm with variable plasma cell infiltration; exudates with leukocytes are present in the anterior chamber (see Systemic Disease, [Chapter 93](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

40.6 THERAPY

Because of the persistent intracellular location of *B. canis*, the outcome of antibiotic therapy of canine brucellosis is uncertain. The organism is susceptible to several antibiotics, but the ineffectiveness of in vivo therapy commonly leads to failures or relapses. None of the treatment regimens is 100% successful. Dogs with brucellosis should *never* be treated with a *single* antibiotic regimen; in all cases, combination therapy should be used. Unfortunately, the most studied regimen (tetracycline plus dihydrostreptomycin) is unobtainable because of the restricted availability of dihydrostreptomycin. Bacteremia often recurs days to months after treatment is discontinued, making follow-up evaluation essential because animals can still harbor infection in certain tissues. The reproductive tissues of the ovary and uterus and testes and epididymis should be surgically removed. In addition, ocular infections may require enucleation of severely affected eyes.

40.6.1 Breeding Animals

It is strongly recommended that infected dogs be isolated and eliminated from breeding programs as soon as a diagnosis is confirmed. Treatment should be considered only under exceptional circumstances, because therapy is expensive and often unsuccessful, especially in chronically infected animals. Aborting females may subsequently produce normal litters, but even in those cases the success of therapy is uncertain. Clinically normal, infected bitches may transmit infection to their surviving offspring. Despite treatment, intact males frequently develop irreversible sterility, making their prognoses as breeding animals poor. Limited studies suggest inability to clear infection in the prostate gland in most instances. Infected female dogs have been reinstated in breeding programs but only after prolonged isolation and therapy and with great risk of failure. The risk of infecting males when breeding with previously infected females has been minimized by judicious artificial insemination. Breeding of such animals should be done only under exceptional circumstances when it is considered essential (e.g., the loss of a valuable blood line) and after the risk is explained to an owner.

40.6.2 Pet Animals

Infected pets should, minimally, be neutered and given a regimen of antibiotic therapy to reduce the chance of infecting family members via genital secretions. The organism can persist in tissues of neutered animals, but shedding is believed less likely. Repeated courses of antibiotic therapy are recommended on the basis of follow-up serologic testing and blood cultures.

Cures of brucellosis must not be assumed because bacteremia may recur weeks or months after antibiotics are discontinued. Attempted culture of bacteria or serologic testing immediately after treatment is halted is deceiving. Reports of successful cures should be viewed with caution unless subsequent cultures and serology have been performed for at least 6 months.

Use of quantitative ME-TAT titers is the best means of monitoring successful elimination of the organism. Testing should be performed at 6- to 9- month intervals after a treatment regimen. Titer values should decrease if therapy is effective. Titers below 1:100 should be reached or else additional courses of treatment are indicated. Corresponding AGID titers results should also become negative. Persistence of increased (more than 1:100) titers should make evoke suspicion that the infection still exists.

Infectious Diseases of the Dog and Cat, 3rd Edition

40.6.3 Antibiotic Therapy

Several drugs have been used to treat canine brucellosis, but the organism is rarely eliminated if the appropriate antibiotic combination and regimen are not used.⁵⁷ Single-antibiotic therapy is not efficacious to eradicate *Brucella* species. By mean inhibitory concentration, in vitro susceptibility has been demonstrated for tetracycline, chloramphenicol, aminoglycosides, spectinomycin, rifampin, third-generation cephalosporins, ampicillin, and fluoroquinolones. Synergy has been noted in vitro among tetracycline and fluoroquinolones and aminoglycosides and sulfonamides.⁵⁰ Infected dogs respond poorly or not at all to those drugs when they are given alone or for a single course of therapy. Relapse occurs within a short time period after therapy is discontinued. Partial in vitro susceptibility occurs with erythromycin, penicillin, novobiocin, and lincomycin. Decreased susceptibility to cephalosporins, nalidixic acid, and cycloserine exists. None of the antibiotics in these last two groups should be given to treat canine brucellosis. Quinolones such as ciprofloxacin, norfloxacin, 378

and enrofloxacin have been shown to be effective in vitro against *Brucella* species,³⁹ but limited in vivo studies have not. Fluoroquinolone monotherapy has been associated with treatment failures and relapses, especially in cases of uveitis or diskospondylitis. Azithromycin has combined with gentamicin to treat brucellosis in people with less efficacy than doxycycline and gentamicin.⁷¹ 379

High-dose oral minocycline or doxycycline therapy combined with intramuscular streptomycin (Table 40-2) has given the highest rate of success in experimentally infected dogs. Lower doses of this combination or other antibiotics alone or in combination were not as effective. Because of the unavailability of streptomycin and its derivatives, gentamicin has been substituted for streptomycin, but efficacy was less than that with dihydrostreptomycin.⁵⁸ Gentamicin is currently used as the most available aminoglycoside for combination regimens. Treatment regimens that are less expensive but generally less effective have been described (see Table 40-2). A longer treatment regimen of tetracycline for 28 days combined with streptomycin for 14 days has had success, especially in treating dogs infected for less than 1 to 2 months.⁵⁷

40.6.4 Diskospondylitis

Localized infections in hard-to-reach areas such as in the intervertebral disk should be treated with at least two or more sequential or intermittent 4-week courses of antimicrobial therapy after neutering. Doxycycline and aminoglycoside combination is recommended for this treatment. Recurrence of hyperesthetic episodes is common in dogs with canine brucellosis diskospondylitis. Owners of infected animals should be cautioned about the potential need for repeated treatment. Surgical intervention is rarely needed unless the diagnostic workup requires obtaining intervertebral tissues for culture. Decompressive surgery should be avoided in paraparetic dogs when possible by first evaluating the clinical response to antimicrobial therapy. Sequential radiography and titers at 3- to 6-month intervals are used to monitor progress. Serologic monitoring should be done with quantitative methods so that relative changes can be detected.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 40-2 Recommended Tetracycline and Aminoglycoside Combination Therapy for Canine Brucellosis^a

DRUG ^b	DOSE ^c (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Tetracyclines				
Minocycline or doxycycline ^{d,28}	25	PO	24	4
	12.5	PO	12	4
Tetracycline ⁵⁷	30	PO	12	4
Aminoglycosides				
Dihydrostreptomycin ^{e,28}	10	IM, SC	12	2 (treatment weeks 1 and 4)
	20	IM, SC	24	2 (treatment weeks 1 and 4)
Gentamicin	2.5	IM, SC	12	2 (treatment weeks 1 and 4)
	5.0	IM, SC	24	2 (treatment weeks 1 and 4)
Streptomycin ^{d,e,57}	20	IM, SC	24	2 (treatment weeks 1 and 4)
Fluroquinolones				
Enrofloxacin	5	PO	24	4
Ocular Involvement				
Rifampin	5	PO	24	4
Prednisone acetate (1%)	1 drop	Topical in eye	8	prn
Gentamicin (0.3%)	1 drop	Topical in eye	8	prn
Flurbiprofen (0.03%)	1 drop	Topical in eye	8	prn
Cyclosporin (0.2%)	1 drop	Topical in eye	8	prn

PO, By mouth; IM, intramuscular; SC, subcutaneous.

- Combination therapy is *always* indicated. One tetracycline and one aminoglycoside should be chosen and administered over a 4-week interval as indicated with the aminoglycoside being given for 2 of the weeks. Dogs should be tested at the end of treatment, and, again 1 and 3 months later. If treatment unsuccessful, improved therapeutic efficacy has been reported by repeating the regimen. Rifampin has been given as a fourth possibility, in combination with either tetracyclines and/or fluoroquinolones in the successful treatment of human and canine brucellosis.⁷⁶
- See [Appendix 8](#), Drug Formulary, for more information on these drugs.
- Dose per administration at specified interval.
- Generic doxycycline may be substituted at the same dose at a lower cost.
- Dihydrostreptomycin and streptomycin are not currently available to veterinarians in the U.S. Gentamicin may be substituted at the dose indicated, but its efficacy is uncertain.

40.6.5 Ocular Infection

Uveal infections with *B. canis* have been exceedingly difficult to treat. No reports have been issued of successful elimination of ocular infection in dogs, as based on an animal becoming seronegative. The organism can be cultured from the aqueous humor in such cases,³⁴ and the ocular tissues are difficult to penetrate, especially with aminoglycosides. Enucleation is required if the eye has been severely damaged because vision will never return and the eye acts as a persistent nidus for the organism. Even use of two antimicrobials is associated with relapse rates of ocular inflammation of 6% to 21%. Multiple-drug combination therapy with doxycycline, gentamicin, enrofloxacin, and subsequent addition of rifampin was successful in eliminating the ocular inflammation in an infected dog.⁷⁶ This finding was the first reported instance of clinical resolution of

379

380

Infectious Diseases of the Dog and Cat, 3rd Edition

the ocular inflammation over 3 years of monitoring. Lesions of inactive chorioretinitis were evident. The AGID titer results were negative; however, the dog still maintained an indirect FA titer of a reduced level suggesting persistence of the organism. Topical or subconjunctival glucocorticoid therapy or topical ocular medications may be needed on a temporary or continual basis to control the intraocular inflammation to prevent irreversible panophthalmitis. Adjunctive topical therapy includes other antiinflammatory drugs such as flurbiprofen or cyclosporine and gentamicin.

40.6.6 Meningoencephalitis

As with other central nervous systems (CNS) infections, therapy with antimicrobials must be at maximal levels to obtain reasonable drug concentrations at the site of infection. Furthermore, as the blood-CNS barrier heals, concentrations will be much more difficult to achieve. Aminoglycosides are of little use in clearing infections from the CNS.

40.7 CONTROL IN INFECTED KENNELS

Control of canine brucellosis in a kennel with cases confirmed by serologic tests and isolation of the organism is a difficult, time-consuming, and agonizing experience for both dog owners and their veterinarians. Difficulties are compounded if antibiotic therapy is instituted when brucellosis is suspected but not confirmed because isolation of *B. canis* becomes uncertain and serologic tests results are questionable. A kennel should be quarantined as soon as the diagnosis of *B. canis* is ascertained, and infected animals should be promptly eliminated. Appropriate disinfection procedures should be implemented to arrest spread of infection via fomites. Persons working with infected dogs and their discharges or secretions in an infected kennel should wear gloves until serotesting can be done to determine the extent of the infection. Animals should not be admitted to or released from the kennel until the disease is eradicated. Movement of dogs within a colony also should be restricted to removal of proven and suspect cases to isolation quarters. New additions are at high risk for infection, especially if dogs are not individually penned, which also increases the number of animals requiring repeated testing during the eradication process. Animals must not be released for sale or any other purpose because they may spread the disease. All dogs in an infected kennel should be serotested for at least 3 months after seronegative status is achieved, especially before each breeding, even if artificial insemination is used. If animals are retained as pets or working dogs, or if treatment is contemplated, they should be neutered and moved to separate housing. Although determining the origin of infections is important, this has proved difficult because of the reluctance of owners to reveal actual or suspected sources.

Carrier dogs are important in maintaining *B. canis* in the dog population because its survival outside the host is short lived, and disinfection with quaternary ammonium compounds or iodophors has been effective in killing the bacterium.

40.8 PREVENTION

In brucellosis-free areas where importation regulations exist, vigilance should be maintained by serotesting incoming animals similar to what has been implemented in evaluating rabies protection and ehrlichial infections.

A dog entering the United Kingdom was later found to be infected.²⁶ Neutered animals pose less of a risk of transmitting infection should they inadvertently enter such areas.

Preventive measures are particularly important in large breeding kennels or wherever a large number of dogs are kept, but no legally mandated control measures exist, and in the United States, canine brucellosis is not a reportable disease in most states. Prevention is accomplished by quarantine of all new acquisitions until two

Infectious Diseases of the Dog and Cat, 3rd Edition

serotest results at a 1-month interval are negative. Animals from kennels known to have had breeding problems should be rejected unless test results are negative.³⁷ Animals with any clinical sign of canine brucellosis should be rejected. Animals used for breeding should be tested 3 to 4 weeks before each mating to allow time for test results to be reported. Brood bitches should not be mated to stud dogs unless they have been tested and certified negative. If dogs leave a colony, they should be tested before readmission. All canine blood donors should be screened for brucellosis because infections have been documented in people by transfusion of contaminated blood products.¹

No vaccine is available, and results of experimental studies have been unsatisfactory. The desirability of a vaccine is questionable, especially when diagnostic testing is available, because an effective vaccine would be required to provide serviceable immunity but not confound the serodiagnosis.

40.9 PUBLIC HEALTH CONSIDERATIONS

Brucella spp. vary in their virulence for people, but exposure to animals or their tissues or secretions is a common denominator. Brucellosis is the most commonly reported laboratory-acquired infection.⁶⁸ Veterinarians can also be infected by accidental inoculation or ocular absorption of the live attenuated vaccines for *B. abortus* or *B. melitensis*. The highest virulence is seen with infections caused by *B. melitensis* and biovars of *B. suis*, while *B. abortus* has a modest virulence. In such infections, spondylitis, polyarthrititis, conjunctivitis, and uveitis are among the more common manifestations of infection. Rare complications include thrombocytopenia, valvular endocarditis, meningitis, pneumonia, neuroretinitis, glomerulonephritis, hepatitis, and visceral abscesses.* Laboratory infection with the *B. maris* group of isolates from marine mammals has been reported.²³

Natural and laboratory-acquired infections with *B. canis* have been reported in several countries; however, the actual number of cases is unknown because human infections are often misdiagnosed.^{15,62,73} Contact with aborting bitches was the source of infection for the majority of infected pet owners, whereas male dogs and undetermined sources were present in other cases. People are relatively resistant to infection with *B. canis*, and the disease is relatively mild compared with infections caused by other *Brucella*. However, infection has even been reported with the so-called *less virulent* laboratory M strain of *B. canis* that is used for serologic diagnosis.⁷⁷ A proportion of human *B. canis* infections are asymptomatic, as determined by serotesting, but the overall rate of infection relative to exposure is low. Fever, chills, fatigue, malaise, lymphadenomegaly, and weight loss have been present in symptomatic patients. In people, *B. canis* infections produce bacteremia, and in some cases endocarditis.⁷⁹ Spondylitis has not been described in people infected with *B. canis*.⁷² Diagnosis of human infections should include bacteriologic examination by blood culture and serologic evaluation. Antibodies to *B. canis* in human sera will react in serologic tests used in dogs and, as in dogs, they do not cross-react with *B. abortus* antigen used in routine testing for human brucellosis. Titers of 1:200 or more, using the ME-TAT, are seen in most active cases. Human infections can be readily and effectively treated with tetracycline therapy. As with infected dogs, people have suffered relapse with ampicillin.

380

381

Clients should always be informed of the potential health hazard in keeping *B. canis*-infected pets. Veterinarians should practice good hygiene when examining suspected dogs, especially aborting bitches.

Laboratory workers should always use personal protection including goggles, masks, gloves and protective clothing and only work with the organism in a biologic safety cabinet. Biohazard precautions should be taken in the laboratory when handling or pipetting samples submitted for diagnostic testing. All waste materials should be autoclaved.

41 CHAPTER 41 Anaerobic Infections

Craig E. Greene

Spencer S. Jang

41.1 ETIOLOGY

Obligate anaerobes are either gram-positive or gram-negative rods or cocci ([Table 41-1](#)). They cannot grow in the presence of molecular oxygen because they do not make superoxide dismutase, and most do not produce catalase. These enzymes are necessary for the breakdown of reactive oxygen intermediates (e.g., superoxide anion, hydrogen peroxide) that are normally generated when bacteria grow in the presence of oxygen. Only species of the genus *Clostridium* form endospores anaerobically, distinguishing them from the genus *Bacillus*, which forms spores under aerobic conditions. The most commonly encountered anaerobes are listed in [Table 41-2](#).

Anaerobes make up a significant portion of the normal bacterial flora of dogs and cats.^{11,49} The predominant microorganisms living on most mucosal surfaces are anaerobes, and metabolic by-products produced by this group of microorganisms are important in the regulation of the numbers of aerobic species (facultative and obligate) that also comprise the normal flora. Thus anaerobic bacteria play an important role in protection of mucosal surfaces from interactions involving other microorganisms with pathogenic potential. For example, approximately 1 million salmonellae are needed to produce disease in animals with intact anaerobic flora, whereas fewer than 10 salmonellae are needed to produce disease in animals with few anaerobes. The importance of this observation is seen clinically; dogs are more prone to develop salmonellosis when they are medicated with antibiotics, especially those effective in reducing the anaerobic component of the normal flora (e.g., ampicillin).⁸⁰

Aside from being responsible for a significant portion of innate immunity (the normal flora), anaerobes may be important participants in clinical disease.^{29,34,39,46,47} Compromise of a mucosal surface by perforation or of a surface or an area contiguous to a mucosal surface may lead to inoculation of members of the normal flora into a normally sterile site. At this point, introduced anaerobes become clinically relevant in addition to other members of the normal flora. These are important facts because antibiotic therapy is almost always started before results of microbiologic analysis of exudative material are received. Therefore an educated guess about the microorganisms present must be made. If anaerobic bacteria are involved in an infectious process, an average of two different species are almost always admixed with aerobic bacteria. The most commonly associated aerobic bacteria are enterics (mainly *Escherichia coli*), members of the genus *Pasteurella*, and coagulase-positive staphylococci ([Table 41-3](#); see Bite Wound Infections, [Chapter 53](#)).

If they contain the appropriate virulence factors, anaerobic bacteria may also produce disease on a mucosal surface. In addition to periodontal disease, anaerobes are associated with disease in other regions of the gastrointestinal tract (see [Chapter 89](#)); the most important of these anaerobes within the intestine are *Clostridium difficile* and *Clostridium perfringens* (see [Chapter 39](#)).^{74,78} Both of these species may be a part of the normal flora of dogs and cats, although evidence suggests that both may be passed to previously uncolonized animals.^{45,60,66}

Infectious Diseases of the Dog and Cat, 3rd Edition

382

Table 41-1 Characteristics of Obligate Anaerobic Bacteria Most Commonly Isolated from Dogs and Cats

MICROORGANISM	GRAM REACTION	SHAPE
<i>Bacteroides</i> spp.	Negative (pale)	Rod
<i>Prevotella</i> spp.	Negative (pale)	Rod (coccobacillus)
<i>Porphyromonas</i> spp.	Negative (pale)	Rod (coccobacillus)
<i>Fusobacterium</i> spp.	Negative (pale)	Rod (usually thin)
<i>Peptostreptococcus anaerobius</i> , anaerobic gram-positive cocci	Positive	Coccus
<i>Clostridium</i> spp.	Positive	Rod (spores)
<i>Eubacterium</i> spp.	Positive	Coccus
<i>Actinomyces</i> spp.	Positive	Rod (spores)

Table 41-2 Species of Obligate Anaerobic Bacteria Isolated from Dogs and Cats

ORGANISM	NUMBER	PERCENTAGE OF ISOLATES (n-316)
<i>Bacteroides</i> spp.	74	23
• <i>B. fragilis</i> group ^a	38	12
• Other <i>Bacteroides</i>	36	11
<i>Peptostreptococcus anaerobius</i> , anaerobic gram-positive cocci	57	18
<i>Fusobacterium</i> spp. ^b	43	14
<i>Porphyromonas</i> spp. ^c	34	11
<i>Clostridium</i> spp. ^d	28	9
<i>Prevotella</i> spp. ^e	16	5
Miscellaneous spp.	39	12

Data compiled from cases from Veterinary Medical Teaching Hospital, University of California, Davis, Calif., 1991–1995.

- a *B. fragilis* was most commonly isolated.
- b *F. nucleatum* was most commonly isolated.
- c *P. asaccharolyticus* was most commonly isolated.
- d *C. perfringens* was most commonly isolated.
- e *P. heparinolyticus* was most commonly isolated.

41.2 EPIDEMIOLOGY

Infectious processes involving a normally sterile site are usually a consequence of “contamination” by members of the normal flora. The composition of the normal flora of the contiguous surface usually mirrors what is found in the infectious process. In human patients, infectious processes involving structures above the diaphragm are more likely to contain anaerobes originating in the mouth, whereas disease below the diaphragm usually involves anaerobes from the intestinal tract.⁷⁵ In animal patients the various species of anaerobes do not seem to have different predilections for a particular site or location.⁴¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 41-3 Most Commonly Isolated Aerobic Microorganisms Associated with Anaerobic Infections in Dogs and Cats

MICROORGANISM	PERCENTAGE OF ISOLATES	
	DOGS (505 ISOLATES)	CATS (85 ISOLATES)
Enterics ^a	29	18
<i>Pasteurella</i> spp. ^b	12	28
Coagulase-positive <i>Staphylococcus</i> spp.	11	7

Data compiled from cases from Veterinary Medical Teaching Hospital, University of California, Davis, Calif., 1991–1995.

- a Most common isolate was *E. coli*, accounting for 70% of the enteric isolates from dogs and 53% of the enteric isolates from cats.
- b Most common isolate was *P. canis*, accounting for 48% of the isolates from dogs, and *P. multocida*, accounting for 75% of the isolates from cats.

Although disease produced by *C. difficile* is the result of its proliferation in the enteric tract of the host after a trigger event (e.g., certain antibiotics and chemotherapeutic agents), epidemiologic evidence from human hospitals suggests that the agent can be spread from patient to patient, resulting in outbreaks of *C. difficile*-associated disease (see Chapter 39).⁷⁰ Such observations imply that the organism either is or has the potential to be contagious. However, determining whether *C. difficile* is truly a contagious pathogen is difficult because it is also found in the enteric tract of clinically healthy animals.^{66,74}

It is unclear whether toxigenic *C. perfringens* is contagious. It likely causes disease by proliferating in the intestinal tract and producing enterotoxin. The trigger that stimulates the proliferation is unknown. What also remains to be determined is whether the source of the agent is endogenous, acquired from another infected animal, or acquired from the environment. The report of outbreaks of *C. perfringens*-associated diarrhea in small animal hospital settings suggests it is contagious, although it is important to remember that some *C. perfringens* are present in the enteric tract of clinically healthy dogs.^{45,78} Detectable levels of *C. perfringens* enterotoxin are not often found in the feces of asymptomatic animals (see Chapter 39).⁷⁸

The genus *Fusobacterium* includes numerous species, one of which—*Fusobacterium nucleatum*—has five subspecies.⁸ One of the new subspecies, *Candidatus Fusobacterium canifelim*, is common in the oral cavity of dogs and cats and has been isolated from dog and cat bite wounds in people. Unfortunately, this organism is often more resistant to quinolones than are human isolates.

41.3 PATHOGENESIS

Anaerobic bacteria cannot live in healthy tissue. On mucosal surfaces (e.g., intestinal tract, gingival crevices, genital tract), they live with other microorganisms that scavenge molecular oxygen, resulting in a local environment with very low pH (a measure of oxygen tension). Likewise, in compromised tissue, inflammatory cells and coinoculated aerobic microorganisms lower the pH sufficiently for anaerobes to grow. Numerous factors that predispose the body to anaerobic infections are listed in Table 41-4.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 41-4 Factors Contributing to Development of Anaerobic Infections

PHYSIOLOGIC INJURY	CAUSES
Immunosuppression	Cytotoxic chemotherapy Glucocorticoid therapy Malignancies Neutropenia Hypogammaglobulinemia Narrow-spectrum aerobic antibacterial therapy Diabetes mellitus
Altered tissue oxygenation	Vascular compromise Hypotension Tissue anoxia GI obstruction or stasis Tissue trauma
Tissue contamination	GI or urogenital perforation Bite or puncture wounds of soft tissues Foreign body migration

Components of anaerobic bacteria have been shown to elicit potent inflammatory responses. Gram-negative anaerobes possess lipopolysaccharides with endotoxic activity, as do their aerobic counterparts. The peptidoglycan of gram-positive anaerobes incites the same inflammatory response as gram-positive aerobic microorganisms. Some anaerobic bacteria produce capsules (e.g., *Bacteroides fragilis*, pigmented *Prevotella* organisms, and *Porphyromonas* organisms), which incite inflammatory responses that result in abscess formation; in other words, capsules without viable bacteria induce abscess formation.⁷⁹ Some evidence suggests that coinoculated aerobic microorganisms induce anaerobe capsule formation. Capsules also play a more traditional role by discouraging association with phagocytic cells.^{7,32}

Aerobic and anaerobic microorganisms can have a synergistic relationship.⁷ Anaerobes act with facultative aerobes such as *E. coli* to induce abscess formation more rapidly than either bacterial group alone. *Actinomyces*, a genus of facultative anaerobes, is commonly found in association with anaerobic infections from foreign body migrations and in association with pyothorax or peritonitis (see Chapter 49). The facultative bacteria lower the oxidation-reduction potential of the tissue environment, facilitating anaerobic proliferation. The necrotic and abscessed tissue may protect the facultative organisms from antimicrobials and body defenses such as phagocytosis. In addition to helping trigger capsule formation, aerobic organisms scavenge oxygen and curtail phagocytosis of the anaerobic component of the sample (and vice versa).⁸¹ Enzymes such as β -lactamase produced by one member of the aerobic-anaerobic partnership protect susceptible microorganisms in the vicinity from being killed by β -lactam antibiotics. These synergistic interactions are important to keep in mind when designing therapeutic regimens, because antibiotic therapy should be directed at both populations for optimal resolution of the infection.

Some anaerobic bacteria produce toxins. *Fusobacterium necrophorum* produces a toxin that forms pores in leukocyte membranes.³² *C. difficile* produces toxins (A and B) that disrupt the cytoskeletal elements of the intestinal epithelial cell, resulting in cell death.^{1,69} *C. perfringens* produces an enterotoxin that interacts with the target cell membrane, resulting in the formation of pores that are made partly by the enterotoxin and partly by the target cell.⁶⁹ Electrolytes are lost through these pores, resulting in reversal of ion and water flow (diarrhea) and finally, death of the cell.

Infectious Diseases of the Dog and Cat, 3rd Edition

Some species of anaerobes produce adhesin molecules (pili or fimbriae).³² These proteins are usually associated with more virulent anaerobes. However, adhesins probably do not play a role other than association with specific sites or locations on mucosal surfaces. Adhesin molecules probably are not expressed and do not have an important role when exposed to phagocytic cells to which they might adhere—an event that leads to phagocytosis and the demise of the anaerobe. In keeping with this model, it has been shown that blood or abscess isolates of *B. fragilis* are rarely piliated, whereas those found on the mucosal surface almost always have pili.⁷

41.4 CLINICAL FINDINGS

Conditions involving anaerobic bacteria infecting a normally sterile site vary according to location, but all involve the formation of a pyonecrotic process. This process stems primarily from the inflammatory response triggered by anaerobe capsule material, cell wall constituents of the anaerobic and aerobic microorganisms that may be present, and thwarted attempts of phagocytosis, leading to deposition of lysosomal contents into surrounding tissue. The most commonly encountered sites of anaerobic isolation are listed in [Table 41-5](#). The clinical findings of such infections are listed in [Tables 41-6](#) and [41-7](#). Exudate from infectious processes that contain anaerobes is often malodorous.

Bacteremia is often associated with seemingly localized anaerobic infections, although it is not often recognized. Animals with intraperitoneal or intrapleural infections experience a systemic spread of organisms into the blood stream. Fever, leukocytosis, hypoglycemia, increased serum alkaline phosphatase activity, and hypoalbuminemia reflect the systemic manifestations of an acute-phase reaction to the anaerobic infection. The hypoalbuminemia may be compounded by loss of serum proteins into effusions or from draining wounds.

41.5 DIAGNOSIS

In addition to clinical features, the cytologic analysis is often helpful in determining whether an anaerobic infection is present. Abundant degenerative neutrophils are usually found with multiple and often morphologically diverse forms of intracellular and extracellular bacteria. Large and filamentous morphology is often typical of anaerobes. Extracellular bacteria may be a result of bacterial contamination of a specimen or contamination of the staining solution. Microscopic evaluation for morphologic shape and Gram staining should be performed when the specimen is collected so that the results can be compared with culture results or the type of organism can be predicted by its shape and staining properties (see [Table 41-1](#)). The standard for determining the presence of anaerobic bacteria in an infectious process is their isolation from clinical samples. They are difficult to isolate in clinical practice unless precautions are taken. Errors in specimen handling and submission are the primary reasons anaerobes are not routinely isolated. Their growth is enhanced by use of an anaerobe chamber, improved transport

383

384

media, and collection practices.⁴ When attempting to isolate anaerobic bacteria, the samples should be handled with extreme care before they are given to laboratory personnel ([Table 41-8](#)). As mentioned, anaerobes are sensitive to oxygen and because of their slow growth are also easily overgrown in samples containing aerobic microorganisms; greater than 70% are mixed. Therefore transport media, transport time, and temperature are important issues (see [Chapter 33](#)). Refrigeration has been shown to be detrimental to the isolation of anaerobic bacteria, thus samples should not be placed at temperatures lower than 4°C. In comparison, aerobic microorganisms in samples maintained at 25°C multiply and in some cases overgrow the anaerobic component. However, at 15°C, aerobes do not multiply to any extent, nor do the anaerobes die. Because swabs tend to dry out and become oxygenated, their use is discouraged. If swabs are used, the tip should be moistened with a prerduced media such as brain-heart infusion broth. The amount of time between sample collection and culture depends on the type of sample, whether transport medium is used, and the volume of the sample. Anaerobic microorganisms

Infectious Diseases of the Dog and Cat, 3rd Edition

in large pieces of tissue or quantities of fluid (greater than 2 ml) are relatively protected from toxic interaction with oxygen and can survive for up to 24 hours before culture, whereas anaerobes in smaller samples or swabs usually cannot. Anaerobic transport media greatly increase the survival of anaerobes and discourage the growth of aerobes. Anaerobic media are available for transport of aspirated material, tissue or biopsy material, and material collected on swabs.⁵⁰

Table 41-5 Relative Frequency of Obligate Anaerobic Bacteria with Respect to Disease Process or Site in Dogs and Cats

DISEASE PROCESS OR ANATOMIC SITE	SPECIES	RANKING	PERCENTAGE CULTURE POSITIVE	PERCENTAGE WITH ANAEROBES
Draining tract	Dog	1	79	39
Pleural fluid	Dog	2	43	31
	Cat	1	44	40
Abscess	Dog	3	81	30
	Cat	2	82	40
Bone	Dog	6	22	6
	Cat	3	46	36
Abdominal fluid	Dog	4	52	19
	Cat	4	50	27
Respiratory tract	Dog	5	50	9
	Cat	5	70	17

Data compiled from Veterinary Medical Teaching Hospital, University of California, Davis, Davis, Calif., 1991–1995; data also reported in Jang SS, Breher JE, Dabaco LA, et al. 1997. Organisms isolated from dogs and cats with anaerobic infections and susceptibility to selected antimicrobial agents, *J Am Vet Med Assoc* 210:1610–1614.

Table 41-6 Clinical Findings Suggestive of Anaerobic Infection

Fever, pain, and swelling
Bite or puncture wound
Foul-smelling wounds or discharges
Gas in tissues or body cavities
Abscess formation
Contiguous infection to mucosal surface with anaerobic microflora
Necrotic or devitalized tissue
Gangrenous tissue
Dark, discolored exudates
Presence of sulfur granules in exudate
Mixed population of organisms or filamentous forms shown by microscopy
Failure to culture organisms with routine methods

At the laboratory, media must be inoculated with specimens as soon as they are received. Use of prereduced, anaerobically sterilized media improves the success of isolation. After inoculation, media is placed in oxygen-free

Infectious Diseases of the Dog and Cat, 3rd Edition

carbon dioxide until it can be put in an anaerobic chamber with an atmosphere of 5% carbon dioxide, 5% hydrogen, and 90% nitrogen. Anaerobic cultivation is time consuming and expensive. The plates must always be handled in an anaerobic hood or a chamber that has been flushed with anaerobic gas. For example, the isolation and demonstration of an anaerobe in a sample containing only one species of anaerobe takes at least 4 days. The cost is approximately \$10 (in American dollars) for media alone. Because most infectious processes contain an average of two different species of anaerobes and at least one aerobe, significantly more effort is required, as is money.

A diagnosis can be made using other methods. Depending on the site, condition, characteristics of the exudate (e.g., odor), and contents observed in stained smears, a presumptive diagnosis of anaerobic bacterial involvement can be made (see [Tables 41-6](#) and [41-7](#) and [Fig. 41-1](#)). When viewed microscopically, some gram-negative anaerobic rods are pale staining and have shapes suggestive of anaerobes—they are often thin, can be sometimes misshapen, and occasionally have pointed ends.

Disease produced by anaerobes while they are on a mucosal surface is somewhat more difficult to diagnose. Isolation from sites where obligate anaerobes are part of the normal flora, such as the oral or pharyngeal cavity, vagina, external auditory meatus, conjunctiva, or skin, can be difficult to associate with pathogenicity. Isolating *C. difficile* and *C. perfringens* harbored in the intestinal tract involves using specialized agar for isolation, immunologic tests to determine the presence of microorganism or toxin in feces or in broth culture, or the polymerase chain reaction for toxin genes in feces or isolates.⁵⁹ (See [Chapter 39](#) for an additional discussion of diagnosis for these enteric clostridial disorders.)

384

386

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 41-7 Comparative Clinical Features of Anaerobic Infections

SITE	PARTICULAR CLINICAL FEATURES	SOURCES
Head and neck	Cranial or cervical abscesses, exophthalmos, pain when opening mouth, subauricular swelling, anorexia, difficulty swallowing, gingivitis and stomatitis, para-aural abscesses, tonsillar abscesses, brain abscesses, inner ear infections, panophthalmitis, meningoencephalitis	Traumatic ear canal separations, ⁵¹ pharyngeal foreign body penetration (stick injuries), ⁶² dental infections, chronic sinusitis, ⁸² tonsillar abscesses, chronic otitis media, ¹⁰ bite wounds, meninges ⁶⁵
Intrathoracic		
Pulmonary	Coughing, fever, dyspnea, lobar or multifocal consolidation (abscesses), hypertrophic osteopathy	Pneumonia, endocarditis, ¹⁸ aspiration pneumonia ²⁷
Intrapleural or mediastinal	Fever, dyspnea, muffled heart sounds, leukocytosis, pyothorax	Penetrating chest injuries, inhaled foreign bodies, esophageal foreign body perforation ^{68,64}
Intraabdominal		
Peritoneal	Fever, abdominal distention, anorexia, intraabdominal abscesses, adhesions	Postoperative foreign suture materials (e.g., silk, multifilament nylon, braided material), ovariohysterectomy, bowel leakage, genital tract infections, actinomycosis
Hepatic	Anorexia, lethargy, vomiting, diarrhea, fever, dehydration, hepatomegaly, mucosal bleeding	Bacteremia, hepatic neoplasia, ascending biliary infection, immunosuppression in diabetes mellitus ¹⁶
Enteric	Chronic diarrhea, blood, mucus	Intestinal stasis, blind loop syndrome, colitis, colonic ulceration
Retroperitoneal	Swelling in lumbar flank, sinus tracts or drainage, pain, fever, anorexia, reluctance to walk	Osteomyelitis of lumbar vertebrae from plant awns, ovarian or uterine ligatures, ⁴³ actinomycosis, ruptured urethra and perirenal abscess
Paraspinal	Pain, reluctance to walk, fever, paresis or paralysis	Usually epidural from local penetration or extension of paraspinal infection, bite wounds, <i>meningitis</i> : less likely anaerobic and often from hematogenous sources
Subcutaneous	Fever, swelling, discharge, leukocytosis	Bite wounds, penetrating injuries (see Chapters 52 and 53)

Fig 41-1 Gram-stained smear of exudate obtained from a cat with pyothorax. The filamentous microorganism (A) is probably *Filifactor (Clostridium) villosus* ^{9,47,76}; the cocci are probably *Peptostreptococcus* (B); and the rods are either an enteric microorganism (e.g., *E. coli*), a nonenteric microorganism (e.g., *Pasteurella*), an anaerobe (*Bacteroides*, *Prevotella*, *Porphyromonas*, *Fusobacterium*), or a combination. Filamentous microorganisms (C) in the chest of a dog would most likely be microaerophilic members of the genus *Actinomyces*.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 41-8 Specimen Collection for Anaerobic Isolation
--

Proper Collection Methods
Percutaneous needle aspiration into deeper tissues
Surgical curettage or scraping of mucosal surfaces
Tissue biopsy of deeper specimens (soft or bony)
Bone sequestrae—deep aspirates of drainage
Female genital tract—(1) laparoscopic or surgical specimens or (2) aspirates
Body fluid aspiration (synovia, peritoneal fluid, plueral fluid, bile, urine)
Lung specimens—always by aspiration or biopsy
Dental or respiratory sinus tissue—should be biopsied or aspirated after decontamination
Specimen Handling
Fluids—injectd via syringe directly into anaerobic transport media
Infected tissue pieces—preferably stored in sterile, capped containers in anaerobic bags
Kept at room temperature, not refrigerated
Transported to the laboratory as soon as possible
Items and Specimens That Should Not Be Submitted
Tissue specimens with abundant microflora (mucosal surfaces)
Contents in plastic syringes
Surface swabs
Nasopharyngeal, gingival, or bronchial washings
Voided urine

41.6 THERAPY

Successful treatment of infectious processes containing an anaerobic microorganism involves medical and surgical interventions (e.g., correction of fluid and electrolyte imbalances, drainage) combined with appropriate antimicrobial therapy. Antimicrobial therapy without surgical drainage is usually unsuccessful. Because anaerobic infections are often polymicrobial, antimicrobial therapy of infectious processes with an anaerobic component should focus on the anaerobic *and* the presumed aerobic components. The most commonly isolated aerobes have been enterics (*E. coli*), members of genus *Pasteurella*, and *Staphylococcus intermedius*.³⁹ The susceptibility of these microorganisms to aerobic antimicrobial agents is shown in Table 41-9. (See Chapter 49 for treatment of infections associated with *Actinomyces* organisms.)

It is difficult and expensive to determine the susceptibility of anaerobes to antimicrobial agents. Guidelines for such testing have been established; however, the assay results have not always been repeatable or consistent for all anaerobic species.²⁶ For these reasons, few laboratories perform such assays (although the disk test is used for therapeutic predictions to determine whether an isolate produces a β -lactamase; Nitrocefin Disc, Difco Laboratories, Detroit, Mich.). In this test a portion of an isolated colony is smeared onto a disk containing a substrate that changes color if a β -lactamase is present. The most common anaerobic β -lactamases are cephalosporinases (which act on first-generation cephalosporins such as cephalexin and cefazolin), penicillin G, ampicillin, and amoxicillin. Clavulanate irreversibly binds to these enzymes. Table 41-10 summarizes the prevalence of β -lactamases found in various anaerobes isolated from dogs and cats.

Data compiled from Veterinary Medical Teaching Hospital, University of California, Davis, Calif., 1994–1995. Determined by use of the E-test (Epsilonometer, AB Biodisk, Solna, Sweden). Results interpreted using interpretive categories and correlative minimum inhibitory concentrations as described by the National Committee for Clinical Laboratory Standards.

Because of the difficulty of antimicrobial susceptibility testing, antimicrobial treatment aimed at the anaerobic component is usually empiric and based on retrospectively acquired data. Anaerobic bacteria are inherently resistant to certain antibiotics (e.g., the aminoglycosides and the quinolones), although extended-spectrum quinolones (e.g., temafloxacin, grepafloxacin, trovafloxacin, cinafloxacin, sparfloxacin, gemifloxacin, and moxifloxacin) and desfluoroquinolones such as garenoxacin act on anaerobic bacteria (see Quinolones, [Chapter 34](#)).^{6,20,21} The most active antimicrobials for anaerobic bacteria are metronidazole, amoxicillin-clavulanate, chloramphenicol, and clindamycin ([Tables 41-11](#) and [41-12](#)).^{26a} Numerous newer β -lactamase inhibitor combinations such as ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam have been shown to be very active against human anaerobic isolates but have not been tested on veterinary isolates.^{3,26a} Drugs in the

387

388

Infectious Diseases of the Dog and Cat, 3rd Edition

broad-spectrum carbapenem group such as imipenem, meropenem, and ertapenem have been very effective in anaerobic infections associated with mixed aerobic populations. Although anaerobes may be susceptible to trimethoprim-sulfonamides in vitro, inhibitors (mainly thymidine) are found in vivo that make this drug combination an unpredictable treatment for anaerobic microorganism infections.³⁷ The tetracyclines are unpredictable as well.²⁹ Isolates of *C. difficile* are susceptible to metronidazole and vancomycin in vitro, and disease produced by this microorganism responds to either drug. Isolates of *C. perfringens* are susceptible to and respond to treatment with the macrolides (tylosin, erythromycin), metronidazole, and ampicillin.⁷⁸ Among the quinolones, only extended-spectrum drugs, such as moxifloxacin and gemifloxacin, and the newer desfluoroquinolones, have reasonable activity against anaerobes at generally used therapeutic dosages.²²

Table 41-12 Drug Dosages for Anaerobic Infections

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)
Penicillin G	Dog and cat	20,000 U/kg	IM, IV	6–8
Amoxicillin-clavulanate ^c	Dog and cat	20 mg/kg	PO	8–12
Cephalexin	Dog and cat	10–20 mg/kg	PO	8
Cefoxitin	Dog and cat	10–20 mg/kg	IV, IM	8
Clindamycin	Dog and cat	5–10 mg/kg	PO, IV	12
Chloramphenicol	Dog	15–25 mg/kg	PO, SC, IV	8
Metronidazole	Dog and cat	10 mg/kg	PO, IV	8

IM, Intramuscular; IV, intravenous; PO, by mouth; SC, subcutaneous.

a See Drug Formulary, [Appendix 8](#) for specific information on each drug.

b Dose per administration at specified interval.

c Recommended to use amoxicillin with clavulanate for anaerobic infections. Other combinations, such as ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam, are also effective.

41.7 PUBLIC HEALTH CONSIDERATIONS

It is estimated that several million people are bitten by dogs and cats every year (see [Chapter 53](#)).¹⁹ Although most of the wounds resulting from animals bites contain aerobic microorganisms, approximately one third contain anaerobes. All are thought to be members of the normal flora of the mouth of dogs and cats. The most common anaerobes belong to the same genera as the anaerobes found in disease processes in dogs and cats.^{19,55} Some members of the oral flora of dogs and cats produce serious disease in immunocompromised individuals and those that are asplenic or have liver disease (see [Chapter 53](#)).

C. difficile is an important cause of disease in human beings. Data indicate that strains of *C. difficile* found in animals are not the same ones found in human patients.^{28,60} No data exist concerning the communicability of *C. perfringens* from dogs and cats to people. However, because it appears that this microorganism can be acquired from contaminated environments, it seems likely but has not been proved that *C. perfringens* from any source can infect dogs, cats, or people. Whether disease results depends on a trigger event, which remains undetermined.

42 CHAPTER 42 Botulism

Jeanne A. Barsanti

42.1 ETIOLOGY

Botulism is a neuromuscular illness resulting from intoxication with a neurotoxin produced most commonly by the organism *Clostridium botulinum*. *C. botulinum* is a group of culturally distinct organisms that are alike only in that they are clostridia that produce toxin with the same pharmacologic properties, even though the toxins themselves are antigenically distinct.^{7,26,39} *C. botulinum* organisms are gram-positive, straight to slightly curved, motile, spore-forming, saprophytic, anaerobic rods that are distributed in soil worldwide.^{7,8} They are 0.5 to 2.0 μm in width, 1.6 to 22 μm in length, with oval subterminal spores.⁷ The spores are resistant to heat, light, drying, chemicals, and radiation. Anaerobic conditions and the appropriate nutrient environment (high quantities of organic material) are necessary for spore germination and cell division. The organism grows best under anaerobic conditions and with warmth (15°C to 45°C), although some strains can grow at temperatures as low as 6°C. The organism produces toxin under anaerobic, low acid (pH over 4.6), and low solute conditions.³⁹

Seven types of *C. botulinum* have been identified, distinguished by the antigenically distinct types (A, B, C1, D, E, F, and G) of botulinum neurotoxin that they produce.^{7,17} All of these types have similar structure and the same neurotoxic effect. The nucleotide sequences for all types have been determined,^{2,39} but the three-dimensional structure of only type A is known.²⁶ Types A, B, E, and F are associated with human disease.^{6,18} Types C and D cause disease in birds and other mammals.^{7,39} Type G has not been confirmed as a cause of disease in any species.⁷ All canine cases to date have been caused by type C toxin, with the exception of two cases of type D reported from Senegal.¹⁸ Although the disease has been experimentally produced in cats,³ no natural cases have been reported. A cat that ate contaminated yogurt did not become ill even though two people eating the same yogurt did.¹² Type C botulism has been reported in lions (*Panthera leo*), but jaguars (*P. onca*) and coatis (*Nasua nasua*), eating the same food as did the lions, were not affected.^{3,11} Most cases of feline dysautonomia have been reported in the United Kingdom, while most canine cases have been seen in the United States. The cause of this syndrome has been elusive. In an outbreak of dysautonomia in a closed colony of cats, immunoglobulin A (IgA) antibody titers to *C. botulinum* surface antigens and toxoid were increased in the ileum and feces of affected compared with control cats.³¹ Toxin was detected in the feces of affected and some subclinical cats but not control cats, even without enrichment culture. In addition, toxin was found in dry cat food. The results support the role of botulinum intoxication in this syndrome.

Usually a single organism expresses a single toxin type.⁸ Types C and D toxins are produced by a *C. botulinum* group that is partially proteolytic and does not ferment glucose.⁸ Although mildly alkaline pH stimulates growth of most types of *C. botulinum*, pH 5.7 may be optimal for type C producing strains.

Botulinum toxins are the most potent, naturally occurring, acutely toxic substances known.² In people, botulinum toxin is 10,000 times more toxic than cyanide⁸ and 15,000 times more potent than sarin gas, used in the terrorist attack in Tokyo.³⁹ Significant differences exist in species susceptibility to botulinum toxin of different types as noted previously. Botulinum toxin is released from vegetative cells only by lysis of the cell or spore. The toxin is not secreted from the cell or spore.⁸ The amount of toxin in spores is only approximately 1% of that found in

Infectious Diseases of the Dog and Cat, 3rd Edition

vegetative cells, but the intrasporal toxin is resistant to heat denaturation. Type C toxin is stable at a pH range from 2.7 to 10.2.²¹ Vegetative cells produced by germinating spores begin to produce toxin within several days after germination. All the different serotypes of botulinum toxin are a single polypeptide of 150 kDa that is inactive when initially released.² All the botulinum neurotoxins are composed of a heavy (H) chain of 100 kDa and a light (L) chain of 50 kDa. The H chain consists of an amino-terminal domain of 50 kDa and a carboxy-terminal end of 50 kDa.⁷ The H and L chain are bridged by a single interchain disulfide bond (Fig. 42-1).^{2,22} Activation is achieved by a specific proteolytic cleavage of a single peptide bond within a surface exposed loop.^{2,36} Bacterial or host proteases can accomplish this cleavage. After cleavage the toxin remains as an associated H and L chain via the disulfide bridge and via noncovalent protein-protein interactions as described in the next paragraph.³² The interchain disulfide bond is essential for toxicity.³⁶

After release from the bacterial cell, the toxin is bound noncovalently with nontoxic proteins to form complexes known as progenitor toxins. The progenitor toxin is very stable at low pH, protecting the neurotoxin from proteolytic attack in the gastric environment. This stability allows the complex to reach the small intestine, where the alkaline pH is conducive to dissociation of the complex, releasing the neurotoxin,^{8,26} which explains why the progenitor toxin is more toxic than neurotoxin alone when administered orally.²² The number and size of the associated nontoxic proteins differ between toxin types. Type C toxin may be associated with up to five additional proteins, resulting in a released complex of molecular size of 500 or 900 kDa.⁸

42.2 PATHOGENESIS

The basis of the production of lower motor neuron (LMN) paralysis in botulism is that the toxin prevents the presynaptic release of acetylcholine at the neuromuscular junction. Both the spontaneous release of acetylcholine and its release caused by a nerve action potential are inhibited.²⁶ Signs of autonomic dysfunction (parasympathetic and sympathetic) co-exist with skeletal neuromuscular dysfunction.²⁶

Botulism is usually caused by ingestion of the preformed toxin, although two variants of the disease in people, infant botulism and infantlike botulism, are caused by *in vivo* production of toxin in the intestine after germination of spores and intestinal colonization with neurotoxicogenic clostridia, not necessarily *C. botulinum*.^{7,16} Normal human adults are resistant to intestinal colonization with *C. botulinum*, largely because of intestinal microflora. Colonization can be induced in adult animals or people only if they are germ free or are being treated with antibiotics.³ Persistent intestinal colonization in adults with *C. botulinum* rarely causes clinical illness.³ Intestinal colonization was established experimentally in 8- to 11-day-old puppies, but no intoxication occurred.³ Intestinal colonization has been found in a natural case of botulism in a 6-month-old dog.³ However, the dog recovered without antibiotic therapy, even though intestinal colonization continued for several months. Wound botulism, in which the organisms infect a wound and produce toxin, is another rare form of botulism in people, usually associated with illicit, injectable drug use.⁷ A concern associated with bioterrorism is that aerosolized botulinum toxin type A can be absorbed through the lungs.³⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 42-1 Schematic drawing of the binding of botulinum toxin by a membrane receptor (R) at the neuromuscular junction (A). The toxin is composed of a heavy chain with carboxyl (HC) and amino (HN) terminal ends and a light (L) chain containing zinc. The carboxyl end of the heavy chain binds to the receptor at the nerve ending (B). The HN terminal end is thought to be involved in the membrane translocation of the L chain into the nerve cell by inserting itself into the membrane lipid bilayer (C). The L chain, free in the cytosol and by its zinc-endopeptidase activity, selectively cleaves SNARE proteins involved in the exocytosis of acetylcholine (C).^{13,18,22} (Courtesy University of Georgia, Athens, Ga.)

The source of botulinum toxin is rarely found in reported canine cases. Type C toxin has been isolated from fly larvae (maggots) and from carrion, and most canine cases are thought to be associated with ingestion of

Infectious Diseases of the Dog and Cat, 3rd Edition

carrion.^{15,18,25} An outbreak in cats was associated with ingestion of carrion.^{14a} Other intoxications are associated with wetlands during warm weather, the areas associated with avian botulism epizootics.³⁴

Once ingested, types C and D toxins are absorbed primarily from upper small bowel into the lymphatic system via endocytosis similar to nutrient proteins. Toxin can continue to be absorbed from the lower small bowel and colon, but this process proceeds more slowly. From the lymphatic system, the toxin enters the bloodstream. The absorbed toxin is in its disulphide-bonded di-chain form.⁸ Neural intoxication occurs in four steps: binding to cell surface receptors by the carboxy-terminal of the H chain, internalization of the toxin into endosomal-like compartments, membrane translocation facilitated by the amino-terminal of the H chain, and enzymatic cleavage of target proteins by the L chain (see Fig. 42-1).

The carboxy-terminal end of the H chain is responsible for binding to the presynaptic membrane (see Fig. 42-1).^{22,31} This end of the H chain is composed of two sub-domains, an N-terminal and a C-terminal.^{8,24} The C-terminal end is the most critical to binding and is the most variable between toxin types, perhaps explaining part of the difference in species susceptibility to different toxins.^{24,36} Binding occurs very quickly and is irreversible, unaffected by temperature and independent of neural activity. The cell membrane receptors for the toxin must have very high affinity for it because only minute quantities (fewer than 10-12 mol) of botulinum toxin are sufficient to cause death.^{18,22} The receptor sites on the neuron are not well understood, but it is postulated that binding requires both polysialoganglioside and other protein components.^{7,8,24} The toxin binds to the presynaptic nerve endings of the peripheral nervous system and cranial nerves.³⁹ Variations in receptor affinity for different types of toxin also help explain the different sensitivities of animal species to the different botulinum toxins.^{18,22,31} During this stage, the toxin is susceptible to inactivation by antitoxin. After binding, the toxin passes through the cell membrane by receptor-mediated endocytosis.⁶ Once inside the cell, the toxin is more resistant to inactivation by antitoxin. However, some experiments show that some types of antibody can enter cholinergic neurons and inactivate internalized neurotoxin.²

390

391

The amino-terminal end of the H chain governs toxin translocation (see Fig. 42-1).²⁵ This process is temperature and energy dependent.³¹ The translocation is pH dependent and requires a low pH step. Low pH triggers a change in the toxin to a state of greater hydrophobicity, leading to ability to penetrate the membrane lipid bilayer.⁸

The L chain is a metallo-protease containing zinc. The blockage of acetylcholine release is caused by zinc-dependent cleavage of protein components of the neuroexocytosis apparatus (the SNARE proteins).^{8,26} The SNARE proteins are essential to the docking and fusion of synaptic vesicles with the presynaptic membrane, events that lead to the release of acetylcholine into the neuromuscular junction.^{7,8} A remarkable finding is that proteolysis of a small amount of the total SNARE present is sufficient to block acetylcholine release.³⁶ Different types of botulinum toxin cleave different bonds within this membrane protein system. Type C toxin targets syntaxin and SNAP-25 proteins, with syntaxin cleavage being most significant.^{26,36} Syntaxin cleavage by type C toxin prevents G-protein regulation of calcium channels associated with presynaptic neurotransmitter release sites. Normally calcium influx through these ion channels stimulates fusion of the vesicles and release of neurotransmitter into the synapse. Thus, with type C toxin, the formation of synaptic vesicles, their number, and their distribution along the presynaptic membrane are all normal, but neurotransmitter cannot be released because the vesicles cannot fuse with the presynaptic membrane.² The life time of intracellular toxin can be quite long; and until the last molecule of the L chain is degraded, toxin-mediated SNARE proteolysis will occur.³⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

Mutations in the amino acid sequence of the toxin targets make them resistant to proteolysis.²⁶ Differences in the targets for the toxins between species are also thought to account for species insensitivity to certain toxin types.

Botulinal neurotoxins do not cause death of the affected neuron. They cause only paralysis and degeneration of the intoxicated synapse. Under light microscopy, no lesions are apparent at the neuromuscular junction. However, changes in terminal axons, synaptic clefts, and adjacent muscle fibers have been noted in neuromuscular junctions by electron microscopy (EM) from human cases. If the animal survives, recovery occurs by reformation of functional neuromuscular junctions. Thus animals with botulism have the potential for a complete recovery of neurologic function with no sequelae.

42.3 CLINICAL FINDINGS

In all species, botulism is characterized by generalized LMN dysfunction, leading to weakness and flaccid paralysis.⁸ Autonomic dysfunction also occurs. In the most severe cases, failure of respiratory muscles leads to death. Botulism should be considered in all dogs with diffuse LMN disease.

The clinical signs in type C canine botulism have been the same whether experimentally or naturally induced.^{3,34,41} The severity of signs varies with the amount of toxin ingested and individual susceptibility. The first sign is a progressive, symmetric, ascending weakness from the rear to the forelimbs that can result in quadriplegia (Fig. 42-2). Tail wag is maintained. A complete neurologic examination will show hyporeflexia and hypotonia, indicating generalized LMN dysfunction. Cranial nerves are often affected: mydriasis with sluggish pupillary responses, decreased jaw tone, decreased gag reflex with excess salivation, diminished palpebral reflexes, and weak vocalization have been found in affected dogs. Pain perception and alert mental attitude are maintained (Fig. 42-3). Unlike inflammatory LMN diseases such as polyradiculoneuritis and polymyositis, dogs with botulism do not show hyperesthesia to muscle flexing, stretching, or palpation. In severely affected dogs, decreased abdominal muscle tone and primarily diaphragmatic respiration may occur.

The heart rate is variable (increased or decreased), and constipation and urinary retention may develop. Megaesophagus has been noted in some affected dogs. Muscle atrophy is variable. No hyperesthesia is present. Conjunctivitis and ulcerative keratitis may develop because of the weak palpebral reflex. Bilateral keratoconjunctivitis sicca has been noted because tear production may be reduced with neurochemical paralysis. Death may result from respiratory paralysis or from secondary respiratory or urinary infections. On necropsy, no gross or light microscopic abnormalities can be seen in the nervous system.

391

392

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 42-3 Dog with botulism showing normal pain perception but lack of a withdrawal reflex. Note the dilated pupil as evidenced by the reflective tapetum. (Courtesy University of Georgia, Athens, Ga.)

The progression of signs is explained by differences in affected muscles, the diaphragm being much more resistant than skeletal muscle to paralysis with progressive neuromuscular blockade.

The incubation period after ingestion of contaminated food in dogs has been from hours to 6 days. The earlier the signs appear, the more serious is the disease. The duration of illness in dogs that recovered has ranged from 14 to 24 days. Cranial nerve, neck, and forelimb functions tend to return first in affected dogs. If recovery occurs, it is complete (Fig. 42-4). Recovery is expected unless secondary infections or respiratory failure occur.

In the reported cases of type D botulism, the dogs died suddenly with signs of generalized hemorrhage and without observed neurologic deficits.³ The signs may have been caused by a different toxin, C2 toxin, which increases vascular permeability and induces hemorrhage and edema.³³

The possible causes of LMN disease in dogs include polyradiculoneuritis, myasthenia gravis, organophosphate toxicity, and tick paralysis. Coral snake venom toxicity and the dumb form of rabies have also been considered in the differential diagnosis.⁹ Although signs in these diseases can overlap, cranial nerve abnormalities and cholinergic signs are more common in botulism than in polyradiculoneuritis or tick paralysis.

Affected cats have shown a similar diffuse ascending LMN paralysis.^{14a} Some cats died with severe signs, whereas cats with less severe illness had marked recovery by 56 hours.

In the dysautonomia associated with Key-Gaskell syndrome in dogs and cats, clinical signs include regurgitation or vomiting, variable anorexia, dysphagia, constipation, urinary retention, and pupillary dilation. In addition to autonomic dysfunction, dogs with this syndrome can also show lower motor neuron paralysis of the skeletal muscle.³¹ Further studies will be needed to substantiate this syndrome is associated with botulism.

Infectious Diseases of the Dog and Cat, 3rd Edition

42.4 DIAGNOSIS

All results of routine laboratory work (complete blood count [CBC], blood chemistry profile, urinalysis) are within reference limits unless secondary complications, such as cutaneous (decubital ulcer) or respiratory (aspiration pneumonia) infections, develop.^{3,34} Cerebral spinal fluid is normal in affected dogs and people. Thoracic radiographs may show megaesophagus in dogs (Fig. 42-5).

Fig 42-4 Dogs recovering from botulism, having regained the ability to resume sternal recumbency and move the head and neck. (Courtesy University of Georgia, Athens, Ga.)

Electromyography (EMG) shows that LMN dysfunction in clinically affected dogs is caused by a problem at the neuromuscular junction and perhaps to peripheral nerve conduction.^{3,43} When a motor nerve is stimulated, motor unit potentials are subnormal in amplitude but not polyphasic (Fig. 42-6). Decrements in motor unit potentials are variable after repetitive stimulation. Fibrillation potentials were noted in one study but not in another,³ which may be related to the difference in the time of performance of EMGs (mean of 16 and 12 days, respectively). Nerve conduction velocity was mildly decreased in one report, even with correction for hypothermia. As the dogs recovered, increased electrode insertional activity and positive sharp waves were found. The main EMG findings in affected people are decreased compound muscle action potentials with normal nerve conduction.³⁴ The most specific EMG test for people is rapid repetitive stimulation: a 50% greater increase in the evoked train of compound muscle action potentials with rapid repetitive stimulation at 50 Hz indicates botulism.¹ Positive results may be found in only one muscle, although many muscles may be weak.⁷ As in dogs, EMG findings in people vary and sometimes lead to incorrect initial diagnoses because findings are relatively nonspecific and experienced electromyographers are essential.³⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

Confirmatory diagnosis of botulism is based on the finding of the toxin in serum, feces, vomitus, or in samples of the food that was ingested. Serum should be collected as early in the disease course as possible and when clinical signs are maximal. Approximately 10 ml of serum or 50 g of feces, vomitus, or food are needed to conduct diagnostic tests. Specimens should be refrigerated, but not frozen unless delay of analysis of several days is likely, and examined as soon as possible. Freezing does not affect the toxin but does affect the ability to detect the organism. Specimens sent to a distant laboratory should be placed in sterile, leak-proof containers and then in insulated shipping containers with coolant. The container should be labeled that it contains a potential biologic hazard, refrigerated on arrival, and should be shipped by the most rapid means available.⁷ Refer to [Appendix 5](#) for a list of laboratories that perform these tests.

Fig 42-5 Lateral thoracic radiograph of a dog with botulism showing megaesophagus. (Courtesy University of Georgia, Athens, Ga.)

Fig 42-6 EMG tracing after stimulation of the right tibial nerve of a dog with botulism. The upper tracing is the response to stimulation at the level of the femoral trochanter, and the lower tracing is the response to stimulation at the popliteal fossa. The amplitudes of the evoked potentials are markedly subnormal.

Infectious Diseases of the Dog and Cat, 3rd Edition

The standard and most reliable method of identifying the toxin remains the mouse inoculation test.^{*} In this test, serum or an extract of feces, vomitus, or food is injected alone and in combination with type-specific antitoxin into the peritoneal cavity of mice. The mice are then observed for signs of botulism. Survival of one group protected with one type of antitoxin and death of the other groups with signs consistent with botulism confirm the presence of botulinum toxin. This test is highly sensitive but is expensive and involves the death of research animals. Safety is also an issue, especially with strains that affect people. Notably, type C toxin has been shown to be as effective as type A in human therapeutic uses³⁵; thus type C toxin may also affect people contaminated via laboratory exposure. Minute quantities of botulinum toxin acquired by ingestion, inhalation, or absorption through the eye or a break in the skin might cause intoxication. Therefore experienced personnel, preferably immunized with botulinum toxoid, must handle all test materials.⁷

With increasing concern about such bioassays, a need has developed for in vitro tests. A variety of enzyme-linked immunosorbent assays (ELISAs) have been developed to measure the endopeptidase activity of botulinum toxin by the cleavage of artificial substrates.^{8,17} These assays have been used to detect botulinum toxin in food in human outbreaks. Some of these assays appear to match the sensitivity and specificity of the mouse bioassay and measure functional toxin.^{8,17} They are more rapid compared with the mouse test. These tests will be important in replacing the mouse bioassay as the diagnostic test of choice when they are validated further and more readily accessible.⁸ Polymerase chain reaction (PCR) assays for toxin are also being developed.¹⁷

An attempt to isolate *C. botulinum* from feces or gastric contents is recommended in people.^{1,7,39} The organism can be isolated from feces of approximately 60% of people with botulism. Isolation of the organism in association with clinical signs provides evidence for the diagnosis, but it is not as conclusive as is toxin identification. Isolation for the organism from food or the environment is usually considered of little significance given that spores are ubiquitous in the environment.³⁹ The type C organism is one of the most difficult to culture because it is a strict anaerobe. The presence of toxin in an extract of cultured feces is often used as evidence of the organism's presence.^{3,12} Because isolation of the organism is time consuming and requires specialized facilities and specifically trained personnel, other ways to identify the organism are being sought. The molecular characterization of the genes for the organisms has led to the possibility that DNA analysis might be useful. PCR-based detection tests have been developed for toxin types A, B, E, and F. However, the potential for false-positive results caused by normally unexpressed genes for toxin production has rendered these tests inadequate for establishing the neurotoxicity of a bacterium. At this point in time, these tests are not being used as routine diagnostic tools in people.⁸ A PCR test for *C. botulinum* type C was used on avian and environmental samples in an outbreak of avian botulism.¹⁹ The results of the PCR test for the organism correlated well with the mouse bioassay conducted after sample enrichment. However, the problem is that the presence of part of the gene from the organism does not confirm that the organism produces neurotoxin.¹⁹

In human beings, at least one laboratory test for botulism was positive in 65% of patients suspected to have the disease. Large outbreaks have occurred in people in which none or only a low percentage of specimens yielded a positive result. Thus, in people, the diagnosis is often made on history and clinical findings.⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

42.5 THERAPY

42.5.1 Supportive Care

Supportive treatment is most important because spontaneous recovery will occur if the amount of toxin ingested is not too large and if respiratory and urinary tract infections can be avoided. If ingestion is recent, removal of material from the intestinal tract via gastric lavage, cathartics, or enemas may be useful. Cathartic agents containing magnesium should be avoided because of the theoretical concern that magnesium may enhance the action of botulinum toxin.³⁹ Affected animals should be assisted to eat, drink, and move about. Waterbeds or cage padding will reduce the incidence of decubital sores. Ability to urinate should be monitored and the bladder expressed as needed. Enemas and stool softeners should be given for constipation. Parenteral fluids should be used as necessary to avoid dehydration, especially if swallowing is impaired. Antibiotics should be provided if infection develops, but aminoglycosides should be avoided because they also have the potential to block neuromuscular transmission. To avoid altering the intestinal microflora, which might allow *C. botulinum* to grow, antibiotics should be given only when necessary.³ Topical nonmedicated or antibiotic ophthalmic ointments should be provided to prevent exposure keratitis in dogs with poor palpebral function. In the most severe cases, mechanical ventilatory support may be needed. Aggressive ventilatory support and meticulous intensive care has lead to markedly improved survival in affected people.⁷

42.5.2 Antitoxin

Antitoxin therapy is most effective if given early in the disease course because equine antitoxin, the only one currently available, is not effective after the toxin has bound to the nerve endings, which occurs rapidly after the toxin is absorbed.⁷ Antitoxin may prevent further toxin binding if intestinal absorption and circulation are still occurring. Because cases in dogs in the United States to date have been type C, that specific antitoxin is needed. Unfortunately, the available antitoxin in the United States is an equine product with antibodies to toxin types A, B, and E³⁹ and thus is not useful in dogs.

42.5.3 Antibiotics

Penicillin or metronidazole has been administered in dogs and people in an attempt to reduce any potential intestinal population of *C. botulinum*.³ The efficacy of these drugs is doubted because disease is usually caused by ingestion of preformed toxin and because neither drug is certain to eradicate *C. botulinum* from the intestine.³ The possibility that these drugs might make the disease worse by releasing more toxin through bacterial lysis or by promoting intestinal infection has also been raised.³ Even in infant botulism, which may involve intestinal colonization with *C. botulinum*, penicillin has no effect on recovery.³ Therefore antibiotic administration is not indicated in the treatment of this disease.

393

42.5.4 Neuromuscular Potentiators

Two drugs, guanidine hydrochloride and 3,4 diaminopyridine, were used in clinical cases in animals, based on literature in people.^{3,12,13} Administration of guanidine hydrochloride to an affected lion resulted in seizures and pyrexia with death 2 days after drug administration.³ Diaminopyridine was given to two lions, with

394

Infectious Diseases of the Dog and Cat, 3rd Edition

improvement in signs for only 30 minutes. That neither of these drugs, or related drugs, will work with type C toxin is now known because they cannot block the specific effect of this toxin. No drug is available for people or animals that counter the effects of botulin neurotoxins.²

42.5.5 Antibody Therapy

Because of the threat of bioterrorism using botulism toxin, a sustained research effort has led to the first compound that can be mass-produced to prevent or treat adult human botulism.¹⁰ Scientists have isolated and identified three antibodies against botulism toxin and combined them. Each antibody is capable of binding to a different part of the toxin, neutralizing the toxin more effectively than a single antibody. A single dose protects people for 6 months, and only small doses are required.

Intravenous administration of human botulism immune globulin is in clinical trials for use in human infant botulism. Infants treated with this product within 3 days of onset of signs recover more rapidly.⁸

Neither of these therapies may be useful in dogs and cats. The antibodies being produced are of human origin and are directed primarily against the toxin types common in people, rather than the type C toxin common in animals. An investigational equine heptavalent botulism immune globulin fragment has been under study.²⁷

42.6 PREVENTION

Heating food to 80°C for 30 minutes or to 100°C for 10 minutes destroys the botulin toxin. Preventing access to carrion and thorough cooking of any food fed to dogs will prevent the disease. Foxhounds appear predisposed to the disease because they may be fed raw meat. Recovered animals do not develop immunity because the amount of toxin necessary to produce clinical signs is so low.⁹

Vaccination with a toxoid against toxin types A, B, C, D, and E has been successful in cattle, abattoir personnel, exposed laboratory workers, and some military personnel.⁸ This vaccine has a significant number of disadvantages. It does not result in equal protection against all serotypes (mainly protects against types A and E), and it requires the production of the active toxin. It is unlicensed, protection requires several months, and immunity is not lifelong.³⁹ Efforts have been directed toward producing recombinant vaccines that can be prepared without isolating toxin from clostridia, and early reports are encouraging.⁸ For example, a recombinant type C variant in which three amino acids were replaced in the L chain was nontoxic to mice and did not cleave syntaxin in vitro.² This product stimulated high antibody levels and protective immunity in mice when given orally or subcutaneously. These studies suggest that new vaccine strategies are possible. Vaccination will probably not be recommended for the general human population because it would block current use of botulism toxin for overactive muscular disorders such as dystonias.

Antibody administration, as described under Therapy, is also being developed for prevention of disease in people.

The recent increased research on prevention is caused by the potential for intentional poisoning. As many as 17 countries are suspected to be developing biologic weapons.³⁹ Botulinum toxin is often one of these agents because it is relatively easy to produce and is highly lethal in small quantities. Whether dogs and cats would be affected in such an attack would depend on the type of toxin and the method of administration.

Infectious Diseases of the Dog and Cat, 3rd Edition

42.7 THERAPEUTIC USE OF BOTULINAL TOXIN

As previously noted, botulinal toxin is used therapeutically in people for dystonias and wrinkling. One canine case of probable essential blepharospasm responded well to botulinum toxin A therapy.²⁸ A total dose of 200 mouse units was used per eye. This total dose was divided and injected with a 25-gauge needle in six subcutaneous sites per eye in the area of the orbicularis oculi muscle. The dog was retreated with 100 mouse units per eye as needed thereafter. The first retreatment was at 1 month, the next at 3 months, and then every 4 months. After more than 3 years of therapy, no adverse effects were noted. Botulinum toxin was evaluated as a potential long-term treatment for excessive mucosal secretions such as in vasomotor rhinitis.³⁸ Type A botulinum toxin (50 units) was packed in a nasal passage of dogs for a 1-hour period. Saline-soaked gauze was a control in the other nostril. When tested by electrostimulation 6 days later, the toxin side had reduced rhinorrhea. Local injection of botulinum toxin have also been evaluated for reducing tone in the sphincter of Oddi controlling biliary retention in dogs.⁴²

43 CHAPTER 43 Tetanus

Craig E. Greene

43.1 ETIOLOGY

Tetanus is caused by the action of a potent neurotoxin formed in the body during the vegetative growth of *Clostridium tetani*. *C. tetani* is a motile, gram-positive, nonencapsulated, anaerobic, spore-forming bacillus. Although strain differences of *C. tetani* exist throughout the world, an antigenically homogeneous toxin is produced by all strains. Resistant spores of the organism can be found in the environment, especially in the soil, where increased moisture, cultivation, and fertilization favor their survival. Organisms are routinely isolated from the feces of many domestic animals, including the dog and cat.⁹ Isolation from human feces occurs with greater frequency in those occupationally exposed to farm animals. Spores can survive adverse weather conditions in the absence of direct sunlight for months or years and can be found readily in dust and debris in indoor environments. Spores are resistant to boiling water, phenol, cresol, and mercury bichloride, and they resist an autoclave temperature of 120°C for 15 to 20 minutes. However, the vegetative phase of *C. tetani* is no more resistant to chemical and physical inactivation than other microorganisms.

43.2 EPIDEMIOLOGY

Tetanus develops when spores are introduced into wounds or penetrating injuries. The spores vegetate in response to anaerobic conditions at the site of injury. The presence of a foreign body, tissue necrosis, other microorganisms, or abscess formation contributes to germination. Two toxins from *C. tetani* have been identified. *Tetanolepsin* causes hemolysis of erythrocytes during rapid in vitro growth of the bacteria; however, it is not considered clinically significant. In contrast, *tetanospasmin* (molecular weight = 176,000) enters the body from the wound site and produces marked effects on neurologic function. It is not absorbed from the gastrointestinal (GI) tract because digestive juices usually destroy it. Its high molecular weight precludes its entry into the placenta.

The prevalence of the disease in dogs and cats is relatively low compared with that in other domestic animals, which may be related to the natural resistance of dogs and cats to this toxin (Table 43-1). The resistance is related to the inability of the toxin to penetrate and bind to nervous tissue; direct central nervous system (CNS) injections of toxin produce the same signs in different species.

43.3 PATHOGENESIS

Many experimental studies have been performed with dogs, cats, and other laboratory animals to elucidate the mechanism by which tetanospasmin enters and affects the CNS. The site and route of administration of toxin are important in determining the type of disease that develops. Localized tetanus can be produced by intramuscular (IM) or subcutaneous (SC) injection of toxin at a specific site. Tetanospasmin is a dimer composed of (1) a heavy chain (100 kDa) that binds to neuronal cells and transport proteins and (2) a light chain (50 kDa) that blocks the release of neurotransmitters.²⁴ Toxin enters the axons of the nearest motor nerves at the neuromuscular end-plate and migrates by retrograde transport within motor axons at a rate of 75 to 250 mm per day to the neuronal cell body within the spinal cord (Fig. 43-1). Within the spinal cord, toxin ascends bilaterally until it reaches the brain (Fig. 43-2).

Infectious Diseases of the Dog and Cat, 3rd Edition

Systemic intravenous (IV) administration of large amounts of toxin usually results in intracranial signs, such as convulsions, facial muscle spasms, or respiratory arrest, before development of generalized limb rigidity. Small amounts of bloodborne toxin are thought to enter the CNS through the intact blood-brain barrier. Alternatively, hematogenously disseminated toxin may localize preferentially in the neuromuscular endings of many motor nerves throughout the body, from which it may ascend by retrograde axonal transport simultaneously into many areas of the nervous system. The initial involvement of facial musculature after hematogenous spread of toxin is explained by the fact that cranial nerve motor axons (e.g., facial nerves) are shorter than those of the limbs. Although all muscles are affected in generalized tetanus, characteristic postures such as outstretched limbs or a closed jaw are observed. The stronger of the opposing muscle groups predominates, such as the extensors rather than the flexors for antigravity support or the muscles used for closing rather than opening the jaw.

The clinical signs of tetanus infection can be explained by the known pathophysiologic effects of tetanus toxin on the nervous system. It inhibits release of glycine and γ -aminobutyric acid (GABA)—neurotransmitters of inhibitory interneurons of the brain and spinal cord. Presynaptic blockade of synapses of Renshaw cells and Ia fibers of alpha motor neurons occurs. Most experimental evidence has confirmed the effect of toxin at the spinal cord; however, the brain, neuromuscular junctions, and the autonomic nervous system can also be affected. Tetanus toxin has an affinity for gangliosides within the gray matter of the CNS, which may explain the cerebral signs that appear in some animals without obvious spinal cord involvement. The effects of tetanus toxin have also been ascribed to its affinity for binding at the neuromuscular junction, which may induce direct neuromuscular facilitation before the migration of toxin to the CNS. Tetanus toxin may affect sympathetic preganglionic neurons in the same way it affects lower motor neurons within the spinal cord, causing signs of autonomic dysfunction. Bradycardia associated with tetanus probably results from vagal-parasympathetic hyperactivity. Tetanus toxin also blocks neurotransmitters in the parasympathetic cardiac inhibitory center of the nucleus ambiguus, resulting in increased vagal tone and pronounced bradyarrhythmias. Increased catecholamine release associated with adrenergic stimulation can also cause episodes of hypertension or tachycardia in tetanus.

395

396

Table 43-1 Relative Susceptibility of Animals to Tetanus Toxin

ANIMAL	SUSCEPTIBILITY ^a
Horse	1 (most susceptible)
Guinea pig	2
Human	3
Mouse	12
Rabbit	24
Dog	600
Cat	7200
Chicken	360,000 (least susceptible)

a The horse has been assigned an arbitrary value of 1, with 1 indicating *most susceptible*. Susceptibility values relate to the comparative amount of toxin required to produce clinical illness, with increasing values indicating decreasing susceptibility.

Fig 43-1 Retrograde intraaxonal transport of tetanus toxin into the CNS. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

The binding of tetanus toxin to presynaptic sites of inhibitory neurons is irreversible; recovery depends on sprouting of new axon terminals.²⁴

43.4 CLINICAL FINDINGS

Clinical signs of tetanus usually occur within 5 to 10 days after receiving a wound, although ranges of 3 to 18 days have been reported.¹⁶ This time varies and is shorter when the wound is closer to the CNS, has numerous organisms, and has a more anaerobic environment, which favors toxin production. Because of the increased resistance of cats and dogs to tetanus, disease onset may be delayed for up to 3 weeks. This delay may account for the absence of a detectable wound at the time of examination. However, because of greater innate resistance of cats, the wound required to produce disease is so extensive that it is usually obvious. Wounds closer to the head (i.e., brain) are associated with more rapid onset and generalized CNS signs than injuries to distant extremities. Tetanus has also been frequently observed as a complication of ovariohysterectomy, pregnancy, or parturition associated with fetal death.^{2,14,16}

396

397

Fig 43-2 Potential routes of tetanus toxin spread into the CNS. (University of Georgia, Athens, Ga.)

Localized tetanus is more common than *generalized tetanus* in dogs and cats than it is in people and other domestic animals because of the relative resistance of carnivores to the toxin. Increased stiffness of a muscle or an entire limb is first noted in close proximity to the wound site (Fig. 43-3). In the thoracic limb the elbow is usually

Infectious Diseases of the Dog and Cat, 3rd Edition

extended, and the carpus may be held flexed or extended. The stiffness usually spreads, gradually involving the opposite extremity. This process usually progresses over a variable length of time and eventually involves the entire CNS.¹⁸ Localized tetanus in the pelvic limbs has been commonly associated with the female reproductive tract of dogs and cats. In animals in which a single extremity is affected, the diagnosis may be unclear.

Animals affected with *generalized* tetanus walk with a stiff gait and generally have an outstretched or a dorsally curved tail. They are not in pain but have difficulty in standing or lying down in comfortable positions because of the extreme muscle rigidity (Figs. 43-4 and 43-5). The rectal temperature is usually increased because of the excessive muscular activity. Postural reaction testing, such as a proprioceptive positioning evaluation, usually reveals normal initiation but stiff performance of the motor response. If the animal is extremely rigid, attempts to correct the knuckled limb may fail. When performing this type of testing, providing weight support is important for obtaining a more accurate evaluation. Myotactic reflexes are generally accentuated and flexor reflexes are depressed, but both may be difficult to elicit because of muscle stiffness.

Fig 43-3 Localized tetanus in rear right limb of dog with postpartum metritis. Stiffness progressed to involve all four limbs as well as facial muscles. (Courtesy University of Georgia, Athens, Ga.)

Intracranial signs develop in the late stages of localized tetanus. They begin earlier in animals with generalized tetanus and usually generalized muscular stiffness. Cranial nerve motor nuclei are affected, resulting in hypertonicity of respective musculature. Protrusion of the third eyelid and enophthalmos result from retraction of the globe, which is caused by extraocular muscle hypertonicity (Fig. 43-6). In addition, miosis is frequently present. The ears are held erect, the lips are drawn back (*risus sardonicus*), and the forehead is wrinkled as a result of facial muscle spasms. Trismus (“lockjaw”) is caused by contraction of masticatory muscles. Increased salivation, increased heart and respiratory rates, laryngeal spasms, and dysphagia can result from involvement of parasympathetic and somatic cranial nerve nuclei.

397

398

Fig 43-4 Characteristic “sawhorse” stance of dog with generalized tetanus.
(Courtesy University of Georgia, Athens, Ga.)

Fig 43-5 Characteristic posture of cat with generalized tetanus, showing stiff limbs and outstretched tail. (Courtesy University of Georgia, Athens, Ga.)

Reflex muscle spasms occur in animals with generalized tetanus or intracranial involvement. Animals become apprehensive and react strongly to tactile or auditory stimulation. Mild stimulation may precipitate periodic generalized tonic contraction of all muscles with opisthotonus or cause grand mal convulsions. When tonic contractions begin to occur, the interval between spasms decreases until the animal reaches a convulsive state.

Infectious Diseases of the Dog and Cat, 3rd Edition

Dogs and cats usually remain conscious until they develop convulsions. Reflex muscle spasms are painful, so animals may vocalize during such episodes. Animals with tetanus usually have a desire to eat but because of jaw stiffness, they may have trouble prehending or swallowing solid food. Animals with complicating hiatal hernia begin regurgitating.^{7,28} Dysuria and urine retention, constipation, and gaseous distention are common results of persistent anal and urethral sphincter contractions. Hyperthermia is a consistent complication from constant muscle contractions or seizures. Nosocomial pneumonia is a common complication of tetanus and is caused by factors such as recumbency, reintubation or tracheostomy, aspiration, use of paralytic agents, or autonomic disturbances.⁴ The progression of clinical signs culminates in death, which is usually caused by respiratory compromise resulting from rigidity of the respiratory musculature, reflex spasms of the larynx, increased airway secretions, and central respiratory arrest from medullary intoxication or anoxia.

Fig 43-6 Pit bull dog with generalized tetanus, showing protrusion of third eyelid and contracture of facial muscles. (Courtesy University of Georgia, Athens, Ga.)

43.5 DIAGNOSIS

History of a recent wound and clinical signs are the primary means of diagnosing tetanus. Wounds that may be present cause hematologic abnormalities, including leukocytosis with neutrophilia and left shift. Serum biochemistry and cerebrospinal fluid (CSF) values are unaffected, although moderate to marked elevations of muscle enzyme (creatine kinase, aspartate aminotransferase) activities may be present. Presumably this elevation results from the muscle injury caused by sustained hypertonicity and recumbency.

Tachyarrhythmias and bradyarrhythmias may be noted in individuals with tetanus. Rapid heart rates are usually associated with sinus tachycardia. Bradycardia (less than 70 beats/min) is characterized by atrioventricular heart block, sinus arrest, and ventricular escape complexes.

Infectious Diseases of the Dog and Cat, 3rd Edition

In dogs that develop hiatal hernia and megaesophagus, thoracic radiographic changes occur in the caudal region and include increased density and esophageal dilation.

The muscle spasms that develop in animals with tetanus are usually reduced but not always abolished by general anesthesia. Deep anesthesia in mildly affected animals may resolve all evidence of muscle hypertonicity. Even when clinically evident relaxation occurs, characteristic electromyographic changes can usually be detected.

Insertion of the needle or tapping of the muscles or tendons is followed by persistent electrical motor unit 398

discharges rather than the expected period of electrical silence. Muscle biopsy results are usually normal in acute 399

cases of tetanus, and any observed abnormalities may be attributed to muscle trauma caused by constant hypertonicity or prolonged recumbency.

Measurement of serum antibody titers to tetanus toxin has been used to substantiate the diagnosis of tetanus. Values must be compared with those from control animals. Such measurements might be helpful in a clinical setting to confirm the cause of undiagnosed muscle stiffness.

Isolation of *C. tetani* from wounds can be a difficult procedure and is unrewarding in a majority of cases. The organisms are usually present in very low concentrations, and although gram-stained smears may demonstrate gram-positive rods and dark-staining spherical endospores, the morphology of *C. tetani* is not unlike that of many other anaerobic bacteria. If culture is attempted, it should be performed under strict anaerobic conditions at 37°C for 12 days. Biochemical reactions or bioassays can be evaluated in an attempt to classify the organism. Mouse inoculation with isolates is not a readily available procedure.

43.6 THERAPY

Therapy for tetanus in severely affected animals is costly and time consuming, and owners must be advised of the possibility of complications and a lengthy hospitalization. Fortunately the disease is often localized or mild in dogs and cats because of their innate resistance. However, untreated cases can prove fatal. Because of their natural resistance, dogs and cats are not vaccinated with toxoid as a means of prophylaxis or treatment. Recommended dosages for the drugs used in the following treatment are summarized in [Table 43-2](#).

43.6.1 Antitoxin

The antitoxin for tetanus consists of antitetanus equine serum (ATS) or human tetanus immune globulin (TIG). In the United States, TIG is approved for IM use, whereas ATS is licensed for IM or IV use. The TIG contains thimerosal and immunoglobulin aggregates and may be more likely to produce reactions when given by other than the IM route.¹

The immediate concern when treating tetanus is administration of antitoxin to neutralize any toxin that has not bound to the CNS or has not yet been formed. The timing and route of antitoxin administration are important in determining the effectiveness of detoxification. Use of antitoxin should be routine; however, the elimination of bound toxin by the affected animal is gradual, and the administration of antitoxin does little to hasten the process. Thus recovery is usually slow and progressive. The dose for prophylaxis is much less than that for treatment. In mildly affected dogs or cats or in those with localized tetanus, antitoxin therapy may not be necessary because of their innate resistance to the toxin.

IV administration of antitoxin is superior to IM or SC administration in producing a rapid and marked increase of circulating antitoxin. It takes 48 to 72 hours for SC-administered antitoxin to reach therapeutic concentrations. The equine antitoxin dose is given slowly over 5 to 10 minutes. Larger animals should receive a

Infectious Diseases of the Dog and Cat, 3rd Edition

proportionally lower dose on the basis of body weight. Total doses greater than 20,000 U do not appear to be more effective because they increase the antigenic mass; they are also more costly.

Unfortunately, IV antitoxin is associated with a high prevalence of anaphylaxis, therefore appropriate precautions should be taken during administration. An initial test dose (0.1 to 0.2 ml) of antitoxin should be given SC or intradermally (ID) 15 to 30 minutes before the administration of the IV dose. A wheal at the site of injection may indicate that an anaphylactic reaction is going to develop. Epinephrine, glucocorticoid, and antihistamine should be readily available in case of an adverse reaction, or glucocorticoid and antihistamine may be given before an antitoxin IV injection if a reaction is anticipated. IV administration of 0.1 ml/kg of epinephrine (diluted 1:10,000) is the drug dose of choice to treat an anaphylactic reaction. It is not advisable to repeat the dose at any time during the course of therapy. A therapeutic blood level of antitoxin persists in dogs for 14 days after the injection, and repeated doses increase the chance of an anaphylactic reaction.

Local IM injection of a small dose of antitoxin (1000 U) around and proximal to the wound site has been shown to be beneficial in experimental studies of localized tetanus.

Intrathecal injection of antitoxin in laboratory animals has been shown to be beneficial in treating tetanus under experimental conditions. Use in affected people has not been proven to be effective.^{1,29} Intrathecal injection of as little as 1% of the recommended IV dose reduced the mortality and morbidity in dogs with mild or moderate tetanus compared with similarly affected animals given IV or lumbar intrathecal injections. The advantage of antitoxin being injected into the CNS and CSF rather than providing a similar systemic dose is that it does not need to penetrate the blood-brain barrier and may partially neutralize bound toxin. Because it is a foreign protein, antitoxin may be toxic in the subarachnoid space. For these reasons, intracisternal therapy should be reserved for severely affected animals.

43.6.2 Antimicrobial Therapy

Local and parenteral antibiotic therapy should be instituted in an attempt to kill any vegetative *C. tetani* organisms present in the wound (see [Table 43-2](#)). Although antibiotics by themselves may not neutralize circulating toxin, they reduce the amount of antitoxin required to treat experimental tetanus once clinical signs are apparent. Penicillin G, the drug of choice, can be given IV in the form of an aqueous potassium or a sodium salt or IM as the procaine salt. A portion of the dose, in the form of procaine penicillin, can be injected IM close to an identified wound site. Because the effectiveness of penicillin on the vegetative organisms may vary, tetracycline has been recommended as an alternative. Penicillin derivatives, such as ampicillin, are not as effective against the organism, and their use may cause little or no response. Metronidazole has been shown to be superior to penicillin G and tetracycline in treating clinical and experimental tetanus, although it has a higher risk for causing toxicity. Metronidazole may be more active and preferred for treatment of tetanus because it is bactericidal, affecting most anaerobes, and builds effective therapeutic concentrations, even in anaerobic tissues. Penicillin is also a known antagonist of GABA, as is tetanus toxin. Clindamycin and tetracyclines are also effective against *C. tetani*, although they are not generally used. The efficacy of fluoroquinolones against *C. tetani* is questionable, so they should not be used. Tetanus in a cat progressed from a localized form to a generalized form despite treatment with enrofloxacin.¹⁹

43.6.3 Sedatives

Various drugs alone and in combination have been given to control the reflex spasms and convulsions associated with tetanus. These drugs also help control the hyperthermia that results from the excessive muscle contractions. An ideal agent is one that controls excitability and spasticity without interfering with voluntary

Infectious Diseases of the Dog and Cat, 3rd Edition

motor function or consciousness. Unfortunately, no such drug is available; however, a combination of phenothiazine and barbiturate comes closest to the ideal.

When provided alone or in combination with barbiturates, phenothiazines appear to be highly effective in controlling the hyperexcitable state. Chlorpromazine is the drug of choice, although acetylpromazine and methotrimeprazine can be given as substitutes. Phenothiazines are ineffective in treating similar-appearing signs caused by strychnine or other causes of convulsions. Tetanus is one exception of a condition for which phenothiazines are used in seizure-prone animals. They are thought to work centrally on the brainstem to depress descending excitatory input on the lower motor neurons within the spinal cord.

399

400

Table 43-2 Recommended Drug Dosages for Tetanus

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Antimicrobials					
Penicillin G	B	20,000–100,000 U/kg	IV, IM, SC	8–12	10
	B	20,000 U/kg	IV	4–6	10
Amoxicillin-clavulanate	B	12 mg/kg	PO, SC	12	10

B, Dog and cat; D, dog; C, cat; IV, intravenous; IM, intramuscular; SC, subcutaneous; PO, by mouth; prn, as needed.

a See [Appendix 8, Drug Formulary](#), for additional information on these drugs.

b Dose per administration at specified interval. Always infuse IV drugs slowly via diluted drip solution or infusion pump. Lowest range value applies to animals with greatest body weight.

c IV route is most preferred and efficacious. Administration of an intradermal or a subcutaneous test dose (0.1–0.2 ml) before IV infusion is recommended to detect hypersensitivity.

d Use as necessary to control bradyarrhythmias.

Infectious Diseases of the Dog and Cat, 3rd Edition

- e Maximum dose IV of 3 mg in any dog.
- f May have to be given IV as a continuous infusion during the early course of treatment.

Barbiturates can be administered for successful control of grand mal convulsions, generalized body stiffness, and opisthotonus, all of which may occur. Pentobarbital may have to be given every 2 to 3 hours, but the actual dose should be adjusted according to the severity of the clinical signs of the patient, because an overdose may unnecessarily suppress the respiration rate and consciousness. Oral or injectable phenobarbital can be given when a longer-acting drug is needed. When a combination of phenothiazine and pentobarbital is used, less barbiturate is needed to control the tetany, although bradycardia can result from this combination. When the heart rate decreases to less than 60 beats/min, glycopyrrolate can be administered as needed to reverse the bradycardia.

Benzodiazepine derivatives such as diazepam or midazolam are alternatives to barbiturates in the control of seizures and nervous hyperexcitability. They block polysynaptic reflexes within the medulla and spinal cord. Methocarbamol is frequently recommended but less commonly used as a central-acting muscle relaxant. It has a relatively short duration of action, as does diazepam. Baclofen, a depressant and antispasmodic that acts as a GABA agonist in the CNS, has been beneficial when given intrathecally to treat severe tetanus in people.^{23,29}

400

401

Dantrolene, a direct-acting muscle relaxant, has been used to control spasticity in human tetanus.^{22,25} It must not be used when underlying hepatic disease is present. Respiratory depression has been a complicating factor in some cases. Curare has only been used in human patients.

Narcotics should never be included in tetanus therapy because they depress the respiratory centers and may stimulate other areas of the CNS. Parasympatholytic drugs such as atropine should also be avoided in routine cases; however, bronchospasm, bronchial hypersecretion, and cardiovascular instability have been controlled by continuous atropine infusions in people with severe tetanus.⁸

Severely affected animals with respiratory compromise from uncontrollable tetanic spasms may be sedated or anesthetized, intubated, and placed on positive-pressure ventilation. These measures often become too costly for owners of veterinary patients and often result in cardiorespiratory complications.

43.6.4 Surgery and Wound Management

Surgery may be required if tissue necrosis or abscess formation is extensive. Antitoxin should be administered before surgery because toxin is released into the circulation during tissue manipulation. General anesthesia is usually required to debride wounds and remove necrotic tissue. Devitalized tissue and visible foreign material should be removed and the wound irrigated. Hydrogen peroxide may be beneficial in flushing the wound because it increases oxygen tension, which inhibits obligate anaerobes. The prognosis for recovery is always greater if the wound site is located and can be debrided.

43.6.5 Autonomic Agents

Autonomic agents are occasionally required to control the cardiac rhythm. Sympatholytic agents generally are not provided in the management of tachyarrhythmias, because other sedatives usually control this complication. Bradyarrhythmia (a heart rate of less than 60 beats/min) that persists can be controlled by short-term administration of a parasympatholytic agent such as atropine or glycopyrrolate as needed. This type of arrhythmia often resolves after a few days in animals that begin to show resolution of their muscle stiffness.

Continuous atropine infusion has been used in the management of severe tetanus in people.⁸ In addition to

Infectious Diseases of the Dog and Cat, 3rd Edition

assisting with cardiovascular arrhythmias, bronchospasm, bronchial hypersecretion, and hypersalivation are reduced. Clonidine, a central-acting sympathoplegic, reduces autonomic dysfunction in tetanus and might benefit severely affected animals.²⁷

Glucocorticoid therapy has never been proven to be beneficial in tetanus and generally should be avoided. In a controlled study of human patients with severe tetanus, betamethasone reduced the need for tracheostomy and ventilation from laryngeal spasm. Hyperbaric oxygenation has been provided for people and dogs with tetanus in an attempt to inactivate *C. tetani*; however, insufficient proof of its benefits exists to justify the time and cost of such a procedure. Neuromuscular blocking agents have been used in humans with tetanus in an attempt to control convulsions or paralyze the patients, who are then placed on artificial respirators. However, this type of therapy is impractical in veterinary medicine because of the intensive monitoring required.

43.6.6 Nursing Care

Supportive measures are imperative in the successful management of an animal with tetanus. Constant nursing may be required for severely affected animals. The animals should be placed in a dark, quiet environment with minimal stimulation. Cages should be shrouded to reduce light, and pledgets of cotton or gauze should be placed in their ears to reduce sound transmission. All therapeutic measures should be coordinated and take place at the same time each day so the least amount of handling and stimulation occurs. Soft, comfortable bedding should be provided because tetanus causes incapacitation, frequently leading to decubital ulcers. Animals should be encouraged to eat and drink on their own. Rinsing the mouth with a solution of 0.1% chlorhexidine acetate helps to cleanse and lubricate the mucosal surfaces. Tetanic animals frequently have difficulty prehending and swallowing solid foods, but they can usually eat blended foods or fluids by sucking through clenched teeth. A stomach tube may be placed if the animal is reluctant to eat, but this is frequently stressful for conscious animals, and esophageal spasm or hiatal hernia may restrict passage of the tube or cause subsequent regurgitation. Only frequently offered, small amounts of food should be given through a stomach tube because of the high risk of gastroesophageal reflux or vomiting and resultant aspiration pneumonia. Animals with tetanus frequently have gastroesophageal reflux, and their laterally rigid posture prevents gravity from assisting their swallowing efforts. A gastrostomy tube may be required for feeding severely affected animals. The hematocrit (HCT) level, plasma protein level, and body weight should be evaluated daily to determine whether adequate fluid balance is being maintained. Balanced polyionic isotonic fluids should be given parenterally to correct any deficits. Parenteral alimentation may be helpful to meet the caloric needs of some animals; however, it requires continual IV administration of special fluids through a central venous catheter and is expensive.

Complications in dogs and cats with tetanus are numerous. Decubital ulcers may develop over bony prominences of recumbent dogs, but they can be prevented by adequately padding the cage and rotating the animal every few hours. Fractures of the long bones, spine, or skull may result from trauma incurred during sudden muscular spasms or convulsions. Other problems include sepsis from IV catheterization and aspiration pneumonia caused by difficulties swallowing. Esophageal hiatal hernia and megaesophagus may result in gastroesophageal reflux and regurgitation. A tracheostomy may be required if breathing is obstructed from laryngeal spasms. Urinary and fecal retention occurs as a result of hypertonic anal and urethral sphincters. Repeated urinary catheterizations may be needed if dysuria or reflex dyssynergia occurs. Intermittent clean catheterization as needed is preferred to maintaining an indwelling catheter because the patient is less likely to establish a bacterial infection. Orally administered simethicone, gastric intubation, and enemas may help relieve GI gas or obstipation. A glutamine solution (10 g per 500 ml of water) can be given orally at a dose of 0.5 g/kg/day on a divided basis by gavage or indwelling tube as a supplement to help maintain GI mucosal integrity. Hyperthermia from generalized muscle contractions may be controlled by parenteral fluids, fans, and

Infectious Diseases of the Dog and Cat, 3rd Edition

application of alcohol to the footpads and pinnae. Nosocomial pneumonia is a serious complication of patients with severe tetanus.⁴ Reasons for its occurrence in animals with tetanus include diaphragmatic immobility, recumbency with atelectasis or aspiration of ingesta, prolonged mechanical ventilation, having tracheostomy, and use of paralytic agents or sedatives.

43.6.7 Prognosis

The prognosis for recovery from tetanus varies depending on the severity of the rigidity at the time therapy is instituted. Most dogs and cats have a self-limiting course of tetanus when rapid and appropriate therapy is instituted. Those with localized tetanus have a better prognosis and more rapid recovery than those with generalized forms. Individuals with rapidly progressing disease have a poorer prognosis.

401

Animals with stiffness that prevents them from maintaining a standing position or walking rigidly without assistance have the most guarded prognosis. Animals with opisthotonus or continual convulsive episodes that cannot move from a rigid lateral recumbent position often are at risk of respiratory arrest. Those with secondary complications are also at risk. The duration, intensity, and cost of treatment are all greater for animals with generalized tetanus. Mortality from complications also is high in those with generalized disease. Improvement after institution of treatment is usually noticeable within 1 week, and gradual but complete recovery is generally noted by 3 to 4 weeks. Occasionally, stiffness persists for longer periods of up to 16 weeks.

402

43.7 PREVENTION

Active immunoprophylaxis with tetanus toxoid is not recommended for dogs and cats; it is used for more susceptible species such as people and horses. Routine tetanus boosters or postexposure prophylaxis is not required. Appropriate care of infected wounds and rational antibiotic therapy should minimize the occurrence of tetanus. Epizootics have occurred in veterinary hospitals that inadequately sterilize their surgical instruments. Cold sterilization of instruments used for surgical procedures should not be used.

44 CHAPTER 44 Leptospirosis

Craig E. Greene

Jane E. Sykes

Cathy A. Brown

Katrin Hartmann

44.1 ETIOLOGY

Leptospirosis, a zoonotic disease of worldwide significance that affects many animal species, is caused by infection with antigenically distinct serovars of the species *Leptospira interrogans sensu lato*, of which at least 10 are of most importance for dogs and cats. Leptospiral nomenclature and taxonomy is complicated. Before 1989, the genus was divided into two species, *L. interrogans*, containing all pathogenic strains, and *Leptospira biflexa*, with all saprophytic strains from the environment. Since that time, the genus has been classified into at least 16 new species on the basis of genetic relatedness (Table 44-1).^{39,113} Both pathogenic and nonpathogenic serovars occur within the same species in this new genetic classification. Over 200 serovars of *L. interrogans* have been described and further classified into antigenically related serogroups. Serogroups currently have no taxonomic basis; however, they have been useful for an epidemiologic tracking and understanding of the disease. Serovars are maintained in nature by numerous subclinically infected wild and domestic animal reservoir hosts that serve as a potential source of infection and illness for people and other incidental animal hosts (Table 44-2). When infected, incidental hosts develop more severe clinical illness and shed organisms for shorter periods. Epidemiologic studies have shown that host preferences can change with time and geographic region of the world.

Leptospire are thin, flexible, filamentous (0.1 to 0.2 μm wide and 6 to 12 μm long) bacteria made up of fine spirals with hook-shaped ends (Fig. 44-1). They are composed of a protoplasmic cylinder that is wound around a straight central axial filament. The outer envelope is composed of lipopolysaccharide (LPS) and antigenic mucoprotein. Leptospire are motile, making writhing and flexing movements while rotating along their long axis.

The most commonly incriminated serovars in canine leptospirosis have been canicola, icterohaemorrhagiae, grippityphosa, pomona, and bratislava, which belong to serogroups Canicola, Icterohaemorrhagiae, Grippityphosa, Pomona, and Australis, respectively. Theories suggest that since the introduction of vaccines containing serovars canicola and icterohaemorrhagiae over 30 years ago, an apparent epidemiologic change in canine leptospirosis has taken place in which dogs are routinely vaccinated, with decreasing reports of disease caused by serogroups Canicola and Icterohaemorrhagiae and increasing reports of disease caused by serogroups such as Australis, Grippityphosa, and Pomona. Serovars canicola and icterohaemorrhagiae were the predominant serovars associated with canine disease at the time vaccination was first instituted, and thus early vaccines contained only these serovars.¹⁹⁷ Emergence of disease associated with other serogroups may stem from several factors, including the use of vaccination and the greater exposure of unnatural hosts such as dogs to wildlife reservoir hosts in rural or suburban environments. Raccoons have been implicated as a source of the serogroup Grippityphosa infections in the northeastern regions of the United States and Eastern Canada.^{118,159,165} Increased testing for these serogroups may also contribute to their increased recognition because before 1970 most assays for dogs only detected serogroups Canicola and Icterohaemorrhagiae. The duration of shedding and potential spread of these serogroups from infected dogs to other dogs or people is uncertain. In serologic surveys, the prevalence of seroreactivity is greater than that of clinical disease, suggesting that subclinical infections occur. In other areas, the

Infectious Diseases of the Dog and Cat, 3rd Edition

prevalence of seroreactivity is low.¹⁴¹ Despite the presence of leptospiral antibody titers in the feline population, clinical reports of leptospirosis in cats are infrequent. Although cats seroconvert after exposure to leptospires, they appear to be less susceptible than dogs to both spontaneous and experimental infections.^{5,55,208}

b Less common serovars for dogs include hebdomadis, javanica, panama, pyrogenes, and tarassovi; for cats include javanica and ballum.

c Guinea pig.

Infectious Diseases of the Dog and Cat, 3rd Edition

44.2 EPIDEMIOLOGY

Leptospire are transmitted between animals by direct or indirect contact. Direct transmission occurs through contact with infected urine, venereal and placental transfer, bite wounds, or ingestion of infected tissues. Crowding of animals, as may occur in a kennel situation, enhances the direct spread of infection. Recovered dogs excrete organisms in urine intermittently for months after infection. Once outside the host, leptospire do not replicate. Indirect transmission occurs through exposure of susceptible animals to contaminated water sources, soil, food, or bedding. The spirochete may remain viable for several months in moist soil that has been saturated with urine. Although evidence exists that spirochetes survive in insects and other invertebrate hosts, the significance of this finding with regard to disease transmission is unknown. The indirect transmission of leptospire may increase when environmental factors favoring the survival of leptospire are optimal.

403

404

Fig 44-1 Ultrastructure of pathogenic leptospire. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Stagnant or slow-moving warm water, although not essential, provides a suitable habitat for spirochetes. Optimal survival in soil is favored by a neutral or slightly alkaline pH. Spirochetes survive only transiently in undiluted acidic urine (pH 5.0 to 5.5), whereas the opposite conditions provide more suitable habitats. Ambient temperatures between 0°C and 25°C favor the survival and replication of leptospires, whereas freezing markedly decreases survival. The temperature and pH requirements for maximal leptospiral survival may explain the apparent increased seasonal incidence of canine leptospirosis in the late summer and early fall^{41,136} and in the southern semitropical belt of the United States and similar climatic regions worldwide. Outbreaks have occurred in association with high rainfall, especially in tropical regions. In the United States and Canada, a correlation was found between a greater number of cases of leptospirosis in dogs at veterinary teaching hospitals and higher average rainfall.²⁰⁶

Several scenarios exist for the occurrence of leptospirosis in dogs and similar observations have been made for the disease in people. Where seasonality exists throughout the world, most cases are observed during warmer months of the year. Because of the water requirement, disease incidence or outbreaks often increase during periods of higher rainfall or flooding, respectively. In arid areas or during drought conditions, infections of accidental hosts are more common around water sources. Infections are observed in rural or suburban dogs that through activities or utility are exposed to standing water, lakes, or streams. Herding dogs, hounds, working dogs, and mixed-breed dogs have been at greatest risk in the United States.²⁰⁷ The number reports of disease in urban-dwelling dogs or dogs used to track scents in urban areas has increased, presumably through their contact with infected rodents or their urine.⁷² Polymerase chain reaction (PCR) has detected infection in rodents from such inner-city areas.⁴ Leptospirosis also appears to be of higher prevalence dogs kept in crowded kennels with unsanitary conditions.¹⁷⁷

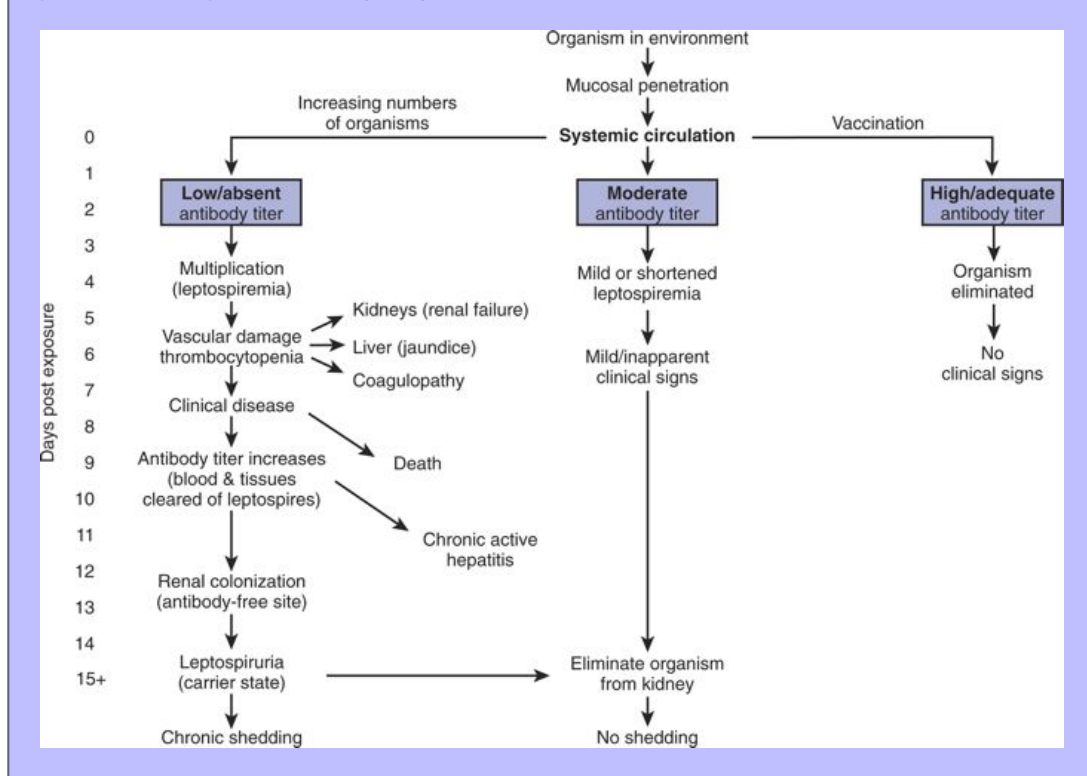

Although the prevalence of clinical leptospirosis in cats is very low, they are probably exposed to leptospires excreted by wildlife. Serosurveys generally show exposure rates of 10% or less. Outdoor cats have the highest seroprevalence. Serovars canicola, grippityphosa, and pomona have been isolated from cats. Cats may also be exposed to urine of cohabitating dogs, and transmission from rodents carrying serovars ballum or icterohaemorrhagiae is suspected.	404 405
--	------------

44.3 PATHOGENESIS

Leptospires penetrate intact mucous membranes of the mouth, nose, or eyes or abraded, scratched, or water-softened skin. They multiply rapidly after entering the blood vascular space (Fig. 44-2). They then spread and further replicate in many tissues, including the kidney, liver, spleen, central nervous system, eyes, and genital tract. The incubation period until clinical signs appear is approximately 7 days but can vary according to the infecting strain and host immunity. Increases in serum antibodies thereafter clear the spirochetes from most organs, but organisms may persist in the kidney and be shed in urine for weeks to months. The extent of damage to internal organs is variable depending on the virulence of the organism and host susceptibility.¹³⁴ Certain serovars have the propensity to produce acute hemorrhagic, hepatic, or most commonly renal involvement. Many animals develop more than one of these clinical manifestations, and disease expression can vary among outbreaks and geographic areas with a given serovar. Tissue edema and vasculitis may occur in rapid and severe infections that result in acute endothelial injury and hemorrhagic manifestations. *Leptospira* LPS stimulates neutrophil adherence and platelet activation,⁹⁴ which may contribute to the inflammatory and coagulatory abnormalities that occur.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 44-2 Pathogenesis of leptospirosis.

Generally, infections of dogs with serovars canicola, bratislava, and grippityphosa have been associated with predominantly renal dysfunction and with minimal liver involvement, whereas serovars icterohaemorrhagiae and pomona produce more hepatic disease. Younger dogs (under 6 months) seem to develop more signs of hepatic dysfunction in any disease outbreak.

Renal colonization occurs in most infected animals because the organism replicates and persists in renal tubular epithelial cells, even in the presence of serum neutralizing antibodies (see Fig. 44-2). The organism penetrates the renal capillaries and enters the interstitium; and by 2 weeks after infection, leptospire may be seen within the proximal tubular cells and tubular lumen, which coincides with the onset of shedding. The invasive capacity of leptospire may be related to their pathogenicity because nonpathogenic leptospire do not penetrate cells as readily as pathogenic leptospire.²¹ Acute impairment of renal function may result from decreased glomerular filtration caused by kidney swelling that impairs renal blood perfusion. Damage to the endothelium of small blood vessels may result in ischemic damage to the renal parenchyma. In addition, several leptospiral factors have a toxic effect on cells located within the renal parenchyma. Significant renal damage probably results from the leptospiral LPS and other outer membrane components. Leptospiral LPS is a potent activator of macrophages, and stimulates secretion of interleukin (IL)-1 and interferon by these cells, in addition to augmenting their killing capacity.⁹⁵ Incubation of peripheral blood mononuclear cells with leptospiral LPS results in the dose-dependent release of tissue necrosis factor- α and IL-10. These cytokines may play a role in the inflammatory response to leptospire.

405

Unsaturated fatty acids in a glycolipid fraction from leptospires specifically inhibit sodium-potassium adenosine triphosphatase ($\text{Na}^+ - \text{K}^+$ ATPase), which might account for the urinary potassium wasting observed in many patients with leptospirosis.^{120,142,214} Endotoxin fractions from *L. interrogans* have been shown to interfere with renal concentrating mechanisms.⁴³

Two hemolysins have been identified in pathogenic leptospires. The first (sphingomyelinase C) was purified from *Leptospira borgpetersenii hardjo*.²⁶ Sphingomyelinase H causes pore formation in target cell membranes, and is highly conserved only in pathogenic leptospires.¹⁰⁹ The extent to which these factors cause tissue damage in leptospirosis remains to be investigated.

Eventual recovery depends on increased specific antibody in the circulation within 7 to 8 days after infection. Animals with adequate functional kidney tissue will recover. Pathologic changes will persist in the severely affected kidney tissue despite clinical improvement. In surviving reservoir hosts, renal colonization will be long term, with shedding in urine for months to years. Although dogs are known to be persistent renal carriers of serovar canicola, the duration of shedding of other serovars has not been determined.

The liver is the second major parenchymatous organ damaged during leptospirosis. Profound hepatic dysfunction may occur without major histologic changes because of subcellular damage produced by leptospiral toxins. The degree of icterus in both canine and human leptospirosis usually corresponds to the severity of hepatic necrosis. In contrast, icterus, hemoglobinemia, and hemoglobinuria that develop in cattle with leptospirosis result from a serovar-specific hemolytic toxin produced by serovar pomona. Decreased osmotic fragility has been detected in canine leptospirosis,¹⁷² making hemolysis less likely.

Chronic active hepatitis has been a sequela to serovar grippityphosa and infection in dogs.²⁹ Dogs in a breeding colony of beagles in France had similar disease from serogroup Australis.² Presumably, initial hepatocellular injury and persistence of the organism in the liver result in altered hepatic circulation, fibrosis, and immunologic disturbances that perpetuate the chronic inflammatory response. Extensive hepatic fibrosis and failure may result from this process. Dogs with hepatic inflammation or fibrosis should be serotested for leptospirosis.

Acute lung injury occurs as a result of the effects of the toxins of the organism on pulmonary tissue. Fluid exudation within the lung may result from vasculitis, and rarely, acute severe pulmonary hemorrhage may occur.²⁸ The degree of pulmonary impairment is often reflective in the prognosis for recovery.^{66,124}

Other body systems are damaged during the acute phase of infection. A benign meningitis is produced when leptospires invade the nervous system. Uveitis occasionally is present in naturally and experimentally occurring leptospirosis. Abortion or infertility resulting from transplacental transmission of leptospires associated with serovar bataviae infection has occurred in a dog.⁵⁸

44.4 CLINICAL FINDINGS

44.4.1 Dog

Table 44-3 summarizes all the clinical features of leptospirosis. Clinical signs in canine leptospirosis depend on age and immunity of the host, environmental factors affecting the organisms, and virulence of the infecting serovar. The clinical severity cannot always be correlated with the serotype of the infecting pathogen. One

Infectious Diseases of the Dog and Cat, 3rd Edition

factor is that the serotypes are genetically heterogeneous throughout the world. Nevertheless, certain generalizations can be made. A comparison of the historical and physical findings is in [Table 44-4](#). Young animals are more severely affected than are adults. Large breed (over 15 kg), outdoor, adult dogs are the most commonly affected.¹³⁶ In a survey of reported cases from veterinary teaching hospitals in the United States, herding dogs, hounds, and working dogs had a higher risk of infection compared with other breeds.²⁰⁷ Peracute leptospiral infections can be exhibited by massive leptospiremia and death with few premonitory signs. In acute infections, pyrexia (39.5°C to 40°C [103°F to 104°F]), shivering, and generalized muscle tenderness are the first clinical signs. Subsequently, vomiting, rapid dehydration, and peripheral vascular collapse occur. Tachypnea, rapid and irregular pulse, and poor capillary perfusion have been noted. Coagulation defects and vascular injury are apparent with hematemesis, hematochezia, melena, epistaxis, and widespread petechiae. Terminally ill dogs become depressed and hypothermic, and renal and hepatic failure does not have time to develop.

Table 44-3 Medical Problems Associated with Leptospirosis *ALT*, Alanine aminotransferase; *AST*, aspartate aminotransferase; *LDH*, lactic (acid) dehydrogenase; *ALP*, alkaline phosphatase.

HISTORY

Young animals more severely affected than adults; large breed, outdoor dogs commonly affected

CLINICAL FINDINGS

Acute: fever 39.5° C to 40° C (103° F to 104° F), shivering, muscle tenderness, vomiting, dehydration, peripheral vascular collapse, tachypnea, rapid irregular pulse, poor capillary perfusion, hematemesis, hematochezia, melena, epistaxis, widespread petechiae, icterus, intestinal intussusception

Subacute: fever, anorexia, vomiting, dehydration, polydipsia and polyuria, reluctance to move, paraspinal hyperesthesia caused by muscular, meningeal or renal inflammation, congested mucous membranes, petechial or ecchymotic hemorrhages, conjunctivitis, uveitis, rhinitis, tonsillitis, oliguria or anuria, coughing or dyspnea, icterus

CLINICAL LABORATORY FINDINGS

Hematology: leukocytosis, thrombocytopenia

Biochemistry: hyponatremia, hypochloremia, hypokalemia or hyperkalemia, hyperphosphatemia, hyperglycemia, ↑ *ALT* activities, ↑ *AST* activities, ↑ *LDH* activities, ↑ *ALP* activities, ↑ bilirubin, ↑ sulfobromophthalein retention, ↑ serum amylase activities (intussusceptions), ↑ serum lipase activities, azotemia

Urinalysis: glucosuria, tubular or glomerular proteinuria, bilirubinuria, ↑ numbers of granular casts, pyuria, hematuria

IMAGING FINDINGS

Interstitial to nodular alveolar densities

Ultrasound of urinary system: renomegaly, pyelectasia, ↑ cortical echogenicity

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *LDH*, lactic (acid) dehydrogenase; *ALP*, alkaline phosphatase.

Subacute infections are characterized by fever, anorexia, vomiting, dehydration, and increased thirst. Reluctance to move and paraspinal hyperesthesia in dogs may result from muscular, meningeal, or renal inflammation. Mucous membranes appear congested, and petechial and ecchymotic hemorrhages are

406

407

Infectious Diseases of the Dog and Cat, 3rd Edition

widespread. Coughing and dyspnea usually accompany conjunctivitis, rhinitis, and tonsillitis. Progressive deterioration in renal function is exhibited by oliguria or anuria. Renal function in some dogs surviving subacute infections may return to normal within 2 to 3 weeks, or chronic compensated polyuric renal failure may develop.

Icterus is more common in dogs affected with the acute form of the disease (Fig. 44-3). Intrahepatic cholestasis from hepatic inflammation may be so complete that fecal color changes from brown to gray. Dogs with chronic active hepatitis or chronic hepatic fibrosis as a sequela to leptospirosis may eventually demonstrate overt signs of liver failure, including chronic inappetence, weight loss, ascites, icterus, or hepatoencephalopathy. Chronic progressive hepatic disease can occur in the clinical absence of other organ system involvement.²

Intestinal intussusceptions occur with some frequency in dogs with acute infections presumably associated with gastrointestinal (GI) inflammation. Careful abdominal palpation should be performed in dogs that develop persistent vomiting and diarrhea. Feces become scanty in such cases, and hematochezia or melena will be apparent.

Fig 44-3 Icterus of mucous membranes of a young pup with acute leptospirosis. (Courtesy University of Georgia, Athens, Ga.)

Pulmonary manifestations include labored respiration and coughing.¹⁶⁴ Both interstitial pneumonia and pulmonary hemorrhage have been documented as the cause in people,^{25,92} and in dogs (Fig. 44-4, A and B).^{23,28}

Infectious Diseases of the Dog and Cat, 3rd Edition

Based on serologic surveys of clinically healthy dogs, a majority of leptospiral infections in dogs are chronic or subclinical.¹⁷⁷ Other medical disorders that subsequently follow subclinical infections such as meningitis and uveitis have been observed in people or other animals.^{48,61} Serologic and microbiologic evaluation for leptospirosis might be performed on dogs with fever of unknown origin, unexplained renal or hepatic disease, anterior uveitis, or meningitis and on healthy dogs in kennels, multidog households, neighborhoods, or other environs where infection in other members has been documented.

44.4.2 Cat

Clinical signs are usually mild or unapparent in feline leptospirosis despite the presence of leptospiremia and leptospiruria and histologic evidence of renal and hepatic inflammation. More widespread testing of cats with acute hepatic or renal disease for leptospirosis may lead to increased recognition of clinical disease in this species.

44.5 DIAGNOSIS

44.5.1 Clinical Laboratory Findings

Hematologic findings in typical cases of canine leptospirosis include leukocytosis and thrombocytopenia. Leukocyte counts fluctuate depending on the stage and severity of infection. Leukopenia, common in the leptospiremic phase, develops into leukocytosis with a left shift. In later stages, white blood cell counts usually range from 16,500 to 45,000 cells/μl. A majority of dogs with leptospirosis have renal failure on initial examination.

Serum urea nitrogen and creatinine increases are found in dogs with varying severity of renal failure (Table 44-5). Electrolyte alterations usually parallel the degree of renal and GI dysfunction. Hyponatremia, hypochloremia, hypokalemia, and hyperphosphatemia are present in most cases, whereas hyperkalemia develops in dogs with terminal oliguric renal failure. In people, hypokalemia in the presence of acute renal failure has been thought to be likely associated with leptospirosis.¹⁴² Similar associations have not been made for the infection in dogs. Mild hypocalcemia is related to hypoalbuminemia and decreased concentration of the protein-bound calcium fraction. Blood pH and serum bicarbonate concentration are reduced in severely affected animals, reflecting metabolic acidosis. Hypoglycemia is occasionally present with severe hepatic failure. Hepatic dysfunction may be apparent in some dogs, but it usually is less dramatic than renal failure or is associated with concurrent renal failure. Liver damage is demonstrated by increased serum alanine aminotransferase (ALT), aspartate aminotransferase, lactate dehydrogenase, and alkaline phosphatase (ALP) activities and bilirubin concentration. The increase in serum ALP activity is often proportionally greater than that of ALT activity. Bilirubin levels may be increased in serum and urine, and the magnitude is usually proportional to the degree of liver impairment. Marked bilirubinuria usually precedes hyperbilirubinemia. Serum bilirubin peaks by days 6 to 8 after onset of disease. Increased sulfobromophthalein retention (more than 5%) can be found in acute leptospirosis before the onset of icterus and in dogs that later develop chronic active hepatitis. Increased serum amylase and lipase activities may result from their release from inflamed hepatic and small intestinal tissues and from decreased renal excretion. Dogs with intussusception have the highest serum amylase concentrations. Serum creatine kinase activity is increased when skeletal muscle inflammation occurs. Urinalysis can be characterized by glucosuria, tubular or glomerular proteinuria, and bilirubinuria and by increased numbers of granular casts, leukocytes, and erythrocytes in the sediment. Some dogs have an increased protein to creatinine ratio in their urine in the presence of an acellular urinary sediment, which indicates the

Infectious Diseases of the Dog and Cat, 3rd Edition

kidney as the source of the urine protein. Leptospires will not be observed in the urine without special staining or darkfield microscopy.

Thrombocytopenia and increased fibrinogen degradation products have been found in dogs experimentally infected with serovar icterohaemorrhagiae. In a majority of dogs, other clotting parameters are normal, suggesting compensated hemostatic mechanisms. Severely affected dogs frequently have vascular endothelial damage with hypofibrinogenemia and thrombocytopenia resulting from disseminated intravascular coagulation (DIC). With meningitis, increased protein concentration with a predominance of neutrophils can be detected by cerebral spinal fluid (CSF) analysis.

In people, assessment of clinical laboratory findings has allowed prediction of severity and mortality in affected patients.^{57,124} Dyspnea and severe alveolar infiltrates on thoracic radiography, elevated blood leukocyte counts, oliguria, and repolarization abnormalities on electrocardiograms are all poorer prognostic findings. Similar associations have not been made for affected dogs.

44.5.2 Radiographic and Ultrasonographic Findings

Although coughing and dyspnea are not consistent features of canine leptospirosis, interstitial to nodular alveolar densities, likely associated with pulmonary hemorrhage from endothelial damage and vasculitis, are found in thoracic radiographs of some dogs.²³ Lesions are most consistently detected in the caudodorsal lung

Infectious Diseases of the Dog and Cat, 3rd Edition

fields. A complete clearance of the lesions occurs in recovered dogs. In decreasing order of prevalence, ultrasonographic abnormalities of the urinary system have included renomegaly, pyelectasia, increased cortical echogenicity, mild perirenal fluid accumulation, and a medullary band of increased echogenicity (Fig. 44-5).⁶³ The medullary echogenic banding is not specific for leptospirosis in dogs and corresponds to a region of renal necrosis and hemorrhage seen grossly and histologically.

409

44.5.3 Serologic Testing

44.5.3.1 Microscopic Agglutination

This standard serologic means to diagnose leptospirosis requires darkfield microscopy, and samples must be sent to commercial laboratories. Organisms grown in liquid media are exposed to serial dilutions of the patient's sera. The end point is the highest serum dilution that causes 50% of the organisms to agglutinate. Contrary to popular belief, the microscopic agglutination (MA) test is a serogroup-specific assay; it does not discriminate organisms at the serovar level.¹¹³ Screening with multiple antigens helps identify the suspected serogroup causing disease in a given patient or population; sera are usually screened at an initial dilution of 1:100. Further twofold dilutions are done against positive-reacting antigens to determine which antibody is present in highest concentration. Many laboratories stop at dilutions of 1:3200; however, others will report the results to end point.

The report to the veterinarian lists the various serovars used as antigens and the respective titers. Dogs with positive titers generally have sera that cross-react to a variety of serovars and that with the highest titer is interpreted as belonging to the infecting serogroup, and lower titers represent antibody cross-reactivity between serovars. Therefore interpreting titers as serogroup specific rather than serovar specific is appropriate. For example, in dogs naturally and experimentally infected with serovar grippityphosa, the

Infectious Diseases of the Dog and Cat, 3rd Edition

highest titer is against this serovar with lower titers to serovars pomona and bratislava. When titers are equal or greater than 1:3200 for more than one serovar, the causative serogroup is classified as mixed and occurs from shared epitopes among organisms of the same group. Unfortunately, if the infecting serogroup is not included as a test antigen, false negative results will occur, or titers may be low because of less affinity to any cross-reacting antigens used. Furthermore, even if the infecting serogroup is included, the MA test does not always correctly identify the infecting serogroup (*paradoxical reactions*).¹¹³ Cross-reactions tend to be worse during the acute phase of the disease; the infecting serogroup is more likely to be identifiable in convalescent sera.

The magnitude expected for a single titer to be positive is always dependent on the background exposure in a population. In any geographic region, measured titers in dogs that are clinically healthy or suffering from other disease syndromes can help with determination and interpretation of background seroreactivity. In some circumstances, background titers may be found from certain serovars that are not associated with clinical disease.¹⁹²

Demonstration of a fourfold increase or decrease in MA titer is classically required for serologic confirmation of an acute, potentially self-limiting disease such as leptospirosis. Many naturally infected dogs will have titers of 1:800 or greater, which on a single specimen is presumptive of leptospirosis with compatible clinical illness and knowledge of no recent vaccinations. Because titers can be negative in the first week to 10 days of acute illness, a second and sometimes a third serum sample should be obtained within 2- to 4-week intervals. Other affected dogs will have high (at least from 1:1600 to 1:12,800) titers when they are hospitalized, with no further increases noted. The magnitude of rise in titer does not always parallel the severity of clinical illness. In some dogs, very high titers or hyperglobulinemia suggests persistence and replication of the organism. Previous infection or vaccination is usually associated with an MA titer of less than 1:400, although higher titers are occasionally observed.¹⁰ If higher vaccination titers (at or above 1:800) develop, they generally do not persist for longer than 3 months, although occasionally titers as high as 1:800 have been observed to persist for 9 months after vaccination.¹⁹⁵ Generally, titers at or above 1:800 indicated active infection or a subclinical renal carrier state. However, some dogs infected with serovar canicola to which they are well adapted may have titers less than 1:400 while being actively infected and excreting organisms.

Antimicrobial therapy very early in the course of disease may decrease the magnitude of the titer rise. Antibody titers will often reduce fourfold over weeks to months after successful antimicrobial therapy of established infections.⁸⁰ Therefore a fourfold increase or decrease in titer is considered indicating active or recent infection. When the renal carrier state has been successfully eliminated, serologic titers will decrease to at the most 1:200 within a 6- to 9-month period, or sooner. Testing of treated animals after this interval is important to determine if the animal is a safe public health risk. Lower levels of antibodies to leptospiral antigens used in the MA test may also indicate some exposure to infection with nonleptospiral spirochetes. Dogs exposed to ticks harboring *Borrelia burgdorferi* that developed high titers to that organism did not show significant increases in titers on the MA test.¹⁸⁵ In contrast, leptospiral infections can affect serotest results for borreliosis when whole-cell assays are used (see Diagnosis, [Chapter 45](#)). A summary of criteria for diagnosis using the MA titer and other testing is in [Table 44-6](#).

44.5.3.2

Enzyme-Linked Immunosorbent Assay

Assay methods such as enzyme-linked immunosorbent assay (ELISA) have been used in dogs to detect IgG or IgM antibodies to leptospires.^{166,209} In comparison, increases in the MA titer parallel the ELISA IgM titer

Infectious Diseases of the Dog and Cat, 3rd Edition

more closely than the IgG titer, although both classes of antibody can cause agglutination. The IgM ELISA increases within 1 week after initial infection, and the maximum titer develops within 2 weeks, with a subsequent decrease thereafter. The IgM ELISA appears to be more sensitive in detecting antibody and is more serogroup specific than the MA test for determining very early infection in dogs. Dogs that died within the first week of illness have had high IgM titers, despite having negative MA titers.

In dogs, increased IgG ELISA titers develop 2 to 3 weeks after infection, with a maximum titer in approximately 1 month. IgG ELISA titers better parallel protection against infection than do MA titers. In contrast to MA and IgM titers, IgG titers increase dramatically after vaccination and persist for many months. By using combined IgG and IgM measurements, the ELISA is better suited to distinguish between natural infection and vaccine-induced immunity than is the MA test. ELISA testing in dogs that have received more than one vaccination demonstrates a high IgG titer accompanied by a low or negative IgM titer, even within the first few weeks after vaccination. The ELISA is not widely available for clinical application. A recombinant antigen-based ELISA method has also been developed that can detect antibodies to a whole variety of pathogenic serovars.^{54a}

Other Immunoassays

A macroscopic slide agglutination test, developed for the diagnosis of human leptospirosis, detects antibodies as early in the course of infection as does the IgM ELISA.³⁸ The advantage of this assay is that it can be used as a field test because it can be done without microscopy. Slide agglutination and indirect hemagglutination assays, available as a commercial kits, have also been used to detect recent or active infections in people and dogs.¹¹⁶ (See [Appendix 6](#).) The slide agglutination and hemagglutination assays may be used on a variety of animals without modification. A commercial screening testing using a broadly reactive leptospiral antigen is incorporated into an ELISA test strip (LEPTO Dipstick assay, Dutch Royal

Infectious Diseases of the Dog and Cat, 3rd Edition

Tropical Institute).^{180,187} This human-specific test strip is a screen for IgM antibodies in serum and has been used in people to determine recent or active infection.

44.5.4 Organism Identification

44.5.4.1 Bacterial Culture

Proper timing and technique are essential for the recovery of leptospires because of their fastidious growth requirements and susceptibility to adverse environmental conditions. Samples should be taken before initiation of antibiotic therapy. Dogs are leptospiremic during the first week of infection, but the numbers of circulating organisms subsequently decrease as serum antibody titers increase. However, urinary shedding develops thereafter.¹⁷³ Occurrence of leptospires in CSF parallels that in blood.¹⁶⁷ Urine is the ideal fluid to be cultured; however, multiple sampling is required because of intermittent shedding of organisms. If animals are adequately hydrated, administration of a low dose of a diuretic such as furosemide (0.5 mg/kg) just before urine collection may facilitate recovery of organisms.

Premortem isolation is preferred because postmortem tissue contaminants will overgrow fastidious leptospires unless selective media are employed. A small volume of tissue (preferably liver or kidney) or body fluid for culture should be collected aseptically in a clean, sterile glass container. Catheterized or voided urine is frequently contaminated by normal flora that interferes with the growth of leptospires; therefore cystocentesis is preferred. Inhibiting substances such as antibody in host tissues and fluids require dilution of the sample by at least 1:10 (vol/vol) with buffered saline, 1% bovine serum albumin, or culture medium. As an alternative, 0.25 to 0.5 ml of blood, urine, or CSF taken at the appropriate stage of infection can be directly inoculated into 7 to 10 ml of transport media. Blood should be anticoagulated with preservative-free heparin or sodium polyethylene sulfonate (as in blood culture bottles) for transport to the laboratory if it cannot be diluted immediately. Citrate anticoagulants should be avoided because they inhibit leptospires. Urine should be alkalinized to pH 8 or greater during transport because leptospires cannot survive acidic conditions for more than a few hours. Tissue or fluid samples, if shipped, should be kept in transport medium or on ice but not frozen. For research purposes, organisms can be frozen in semisolid or transport media and stored at temperatures of -60°C to -70°C for up to 6 years before culture.

Media for isolation of leptospires are liquid, semisolid, or solid in nature. Ellinghausen, McCullough, Johnson, Harris (EMJH) is a liquid or semisolid medium containing polysorbate 80 and fetal calf serum or bovine serum albumin. Modification of standard medium by adding antibiotics or 5-fluorouracil has produced improved results in isolation of certain leptospiral serovars. Leptospires commonly lose their virulence on culture in artificial media, but this loss can be reversed by passage in susceptible animals. Culture of spirochetes from tissues or body fluids is not by itself diagnostic of clinical illness because leptospires can be recovered from both fluids and tissues of healthy dogs.

Identification of the infecting serovar requires application of serologic or genetic typing techniques following isolation. MA test with polyclonal or monoclonal antibodies is the best means of serologic classification. Pulsed-field gel electrophoresis following restriction digestion of full-length chromosomal DNA accurately types serovars, and is more rapid than serologic methods.^{49,90}

Infectious Diseases of the Dog and Cat, 3rd Edition

44.5.4.2 Microscopic Evaluation

Darkfield examination is necessary for rapid identification of viable leptospires because they cannot be stained by simple methods with aniline dyes. Wet-mount preparations are also necessary to help characterize their writhing and flexing movements. A variety of bacteria that can be confused with leptospires produce more random movement in wet-mount preparations. Cellular fibrils or extrusions and fibrin strands can be mistaken for organisms. Darkfield microscopy can also fail to detect active infections because approximately 10^5 organisms/ml are required.³² Centrifugation can be used to concentrate specimens. Because of the inaccuracies of darkfield examination, it should always be followed by cultural or serologic procedures. Because of these inaccuracies, darkfield examination is no longer recommended.

Leptospires can be seen by light microscopy in tissue sections or on air-dried smears with Giemsa stain or silver impregnation.

Direct fluorescent antibody (FA) techniques have been adapted to identify leptospiral serovars in tissues imprints of liver and kidney and in body fluids such as blood or urine (Fig. 44-6). Direct FA testing can be used as a screening method to identify animals shedding organisms in urine when culture is impossible or too time consuming. Organisms may not be shed in urine until 4 to 10 days after the onset of clinical signs. Generally, available conjugates do not discriminate among serovars, and the method cannot differentiate viable and nonviable organisms.

44.5.4.3 Immunodetection

Agglutination-adsorption techniques using monoclonal antibodies have been employed in specialized laboratories to serotype isolates. Antigen capture using similar antibodies in dot ELISA has been developed to detect *Leptospira* antigen in urine of infected people.¹⁷⁰ Although not widely available, this method is highly sensitive and specific and can be used at low cost without specialized equipment.

44.5.4.4 Genetic Detection

Leptospires have been detected in biologic fluids by the very sensitive PCR. PCR can be used to rapidly differentiate pathogenic from nonpathogenic isolates.¹⁴⁹ Genetic methods allow for more specific determination of the infecting strains, which is not possible with measurement of serum antibody titers. Genetic probes have been used to detect leptospires in blood, CSF, aqueous humor, and urine.^{18,131,167} PCR has been used to detect leptospires in the aqueous humor of people and horses with uveitis.^{48,61} Because of higher concentration of leptospires in urine, testing that fluid is essential to ensure the accuracy of genetic detection methods. In people, PCR is more reliable than serologic testing or culture of urine for very early diagnosis.⁴² Multiplex or arbitrarily primed PCR methods have been sensitive and specific for detection of leptospires in canine urine.^{44,81,82,111} Although some of these assays offer the advantage of rapid speciation of the infecting organism, discrimination at the serovar level has not been possible. Magnetic immunocapture has been used to increase the sensitivity of PCR detection.¹⁹⁶ Restriction endonuclease analysis of DNA amplified using PCR has allowed differentiation between many serovars and has the potential to be used on DNA obtained directly from clinical samples. Unfortunately, some of these methods have failed to detect certain serovars, and others did not permit differentiation of all-important serovars infecting dogs. PCR methods such as arbitrarily primed PCR have allowed epidemiologic tracking of the source and commonality

Infectious Diseases of the Dog and Cat, 3rd Edition

of particular strains involved in disease outbreaks in people.¹⁵¹ PCR results in urine have been more sensitive in giving positive results than those of MA testing of sera in evaluating dogs with suspected leptospiral infection.^{81,82} As with culture, PCR results may have false positive results and may detect organisms in subclinical carriers. Therefore positive results must always be interpreted in light of the clinical signs. Furthermore, genomic sequences of nonviable *Leptospira* can be detected in recovered or treated dogs. Further studies are needed to determine the sensitivity and reliability of this method for diagnosis.

Fig 44-6 Direct FA stain of leptospires in the kidney (×60). (Courtesy Wayne Roberts, University of Georgia, Athens, Ga.)

44.6 PATHOLOGIC FINDINGS

External gross lesions vary greatly depending on the severity of the disease and may include congested and icteric mucous membranes with diffuse petechiae. Focal ulcerations may be seen on the tongue and in the buccal cavity and are likely secondary to uremia. Tonsillar or lymphoid tissue enlargement may be present. Kidneys are enlarged in animals that die of acute infection. They are pale and yellow-gray in color and bulge on the cut surface (Fig. 44-7). The renal capsule may be adherent to the surface of the kidneys, and subcapsular hemorrhages are common. In less acute cases, focal, white spotting may be seen in the renal cortex on cut sections and is most prominent along the corticomedullary junction. In chronically infected or treated and recovered dogs, the kidneys may be scarred and shrunken (Fig. 44-8). Leptospires can be cultured from macerated kidney tissue. More commonly, with serovar icterohaemorrhagiae infection, the respiratory tract may be edematous with pulmonary congestion, and spotty, diffuse, pneumonic infiltrates may be present. Petechial and ecchymotic hemorrhages are commonly found on the pleural surface (see Fig. 44-4, B). With hepatic involvement, the liver is enlarged and friable, with pronounced interlobar markings and yellow-brown discoloration (Fig. 44-9). Petechiae and ecchymoses are found throughout the leptomeninges. Ulcerative and hemorrhagic gastritis is often present in uremic animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

Necrosis and hemorrhage are occasionally present in the bowel with intestinal intussusceptions. Free blood or acholic feces may be found in the colon and rectum of some animals. The spleen may be pale and shrunken.

Some variability exists in the histologic appearance of the kidney; this variability is attributed to the virulence of the infecting serovar and the duration of the infection. Dogs with acute leptospirosis, which occurs before a significant serologic response (i.e., titers are frequently negative), have severe renal dysfunction. Histologically, however, the renal lesions are subtle, consisting of mild renal tubular necrosis and interstitial edema. Interstitial inflammation is absent or minimal. Secondary lesions of uremia, such as pulmonary mineralization, gastric mucosal mineralization, and vascular fibrinoid necrosis, are common. Severe multifocal pulmonary hemorrhage is apparent (Fig. 44-10). The subacute form of leptospirosis is characterized by diffuse interstitial renal inflammation, which is most severe at the corticomedullary junction (Fig. 44-11). The infiltrate is composed primarily of plasma cells, with lesser numbers of lymphocytes and macrophages. Scattered neutrophils and necrotic epithelial cells are often present within tubular lumina. Kidneys of chronically affected dogs are characterized primarily by diffuse renal interstitial fibrosis, with only mild to moderate multifocal lymphoplasmacytic inflammation, and scattered macrophages. These histologic lesions of more chronic leptospirosis are nonspecific and are found in most end-stage kidneys.

Fig 44-11 Renal lesions of subacute leptospirosis. Renal tubules in the deep cortex are separated by a large number of plasma cells, small numbers of macrophages, and scattered neutrophils (H and E stain, $\times 400$). (Courtesy Cathy Brown, University of Georgia, Athens, Ga.)

Special stains are needed to visualize leptospires in tissues. With silver staining, which is relatively nonspecific, globular debris and intact spirochetes can be found adhered to the luminal surface of renal tubular epithelial cells. Intact organisms are most often detected in subacute cases; silver stains often fail to detect organisms in acute or chronic cases. Although no more sensitive than silver stains, immunohistochemical stains are highly specific for

Infectious Diseases of the Dog and Cat, 3rd Edition

detecting leptospires.²¹⁰ Immunohistochemical staining is uniformly positive in subacute cases, appearing primarily as globular material within tubular lumina, tubular epithelial cells, and interstitial macrophages. Widely scattered intact organisms may be detected in clumps or individually within tubules in some but not all subacute cases (Fig. 44-12). Positive staining material is also seen in the inflammatory foci in chronic leptospiral renal disease. Leptospiral antigen is detected immunohistochemically in some, but not all, of the acute cases. FA examination of unfixed kidney is a more sensitive, widely available, method for detecting leptospiral antigen and will detect both intact organisms and leptospiral debris.

Histologic changes in the lung consist of fibrinoid necrosis of blood vessels and perivascular, intraalveolar, and subpleural hemorrhages. Mononuclear cell infiltrates surround thrombosed pulmonary vessels. Focal necrosis of hepatic parenchyma may be present. Hepatocytes are rounded, with pyknotic nuclei, and contain an eosinophilic granular cytoplasm. Intrahepatic bile stasis and severe hepatocellular injury are usually evident in icteric animals. The clinical severity of hepatic disease parallels the severity of histologic changes in the liver. Subclinical cases usually have mild fatty changes in hepatocytes, whereas moderately ill dogs have fragmented hepatic cords, with lymphocytic infiltrates in areas of necrosis, and severely affected dogs have widespread necrosis of hepatic parenchyma and disintegration of nuclei. Chronically infected dogs develop chronic active hepatitis and hepatic fibrosis. Organisms may be demonstrated in intercellular locations within hepatic cords.

413

414

Fig 44-12 *Leptospira* immunohistochemistry; subacute leptospirosis. Large clumps of positive staining debris and occasional intact spirochetes (*arrows*) are present within tubules, in addition to prominent globular intraepithelial staining (*arrowheads*) (peroxidase, $\times 60$). (Courtesy Cathy Brown, University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Neurologic damage includes perivascular hemorrhage (uncommon in the cat), mononuclear cell infiltrate, and occasionally, vascular thrombosis. When a silver stain is applied, leptospires can be found in pericapillary areas. Although gross lesions are absent in the heart, focal lymphocytic myocarditis may be evident on histologic examination.

Immunohistochemical procedures that have been developed to detect leptospires in canine tissues²¹⁰ have been effective on formalin-fixed specimens, and the monoclonal antibodies provide a high degree of specificity.

44.7 THERAPY

Supportive therapy for animals with leptospirosis depends on the severity of infection and the presence of renal or hepatic dysfunction and other complicating factors. Dehydration and shock occur in severely affected animals. Placement of a jugular or central venous catheter is usually recommended to assist with repeated sampling, high-volume fluid administration, and measurement of central venous pressure. Indwelling urinary catheters may be needed in oliguric animals to obtain precise measurements of urine output; however, they often result in complicating nosocomial bacterial infections. Fluid loss results from vomiting and diarrhea, and balanced polyionic intravenous (IV) fluids should be used to correct the deficits. Oral alimentation must be discontinued in vomiting animals. Uremia and uremic gastritis are chemical and visceral causes for vomiting in these animals. Centrally acting antiemetics and parenterally administered gastric protectants (e.g., H₂-receptor blockers, proton-pump inhibitors) may be needed; however, oral administration of gastric protectants may be impossible if vomiting persists. Petechial and ecchymotic hemorrhages indicate thrombocytopenia from vasculitis or DIC in severely affected animals. Plasma or fresh whole blood transfusions should be given with caution and only with concurrent low-dose heparin for ongoing DIC or severe hypoalbuminemia.

Oliguria (under 2 ml/kg/hr) and anuria are treated initially with rehydration. Osmotic diuretics, such as 10% to 20% glucose (5 ml/kg) or 20% mannitol (0.5 g/kg), should be given IV over 30 to 60 minutes when impaired renal function persists after rehydration. If treatment with these diuretics fails, dopamine (5 µg/kg/min) or dopaminergic agents may be administered by IV infusion. Tubular diuretics such as furosemide (2 to 4 mg/kg) should be administered parenterally in conjunction with dopamine to increase urine flow; however, the effect on improving glomerular filtration is debated. An essential element is that fluid therapy be adjusted to the individual patient's urine output. Peritoneal dialysis or preferably hemodialysis (when available) should be considered if oliguria persists because acute renal dysfunction is potentially reversible.³ Predicting which dogs will respond to fluid diuresis is not always possible based on laboratory values.

In people, massive pulmonary hemorrhage is often associated with high mortality. Adjunctive therapy has consisted of hemofiltration to remove cytokines and use of nitric oxide inhalation to help open up blood-filled alveoli.⁶⁶

Antibiotics usually reduce fever and bacteremia within a few hours after administration. They immediately inhibit multiplication of the organism and rapidly reduce fatal complications of infection such as hepatic and renal failure. The sooner in the course of infection that antimicrobial agents are used, the better the chance is for reversal of tissue injury caused by the spirochetes. Therefore this therapy should be instituted immediately on suspicion and before return of definitive testing results. In vitro and experimental in vivo susceptibilities exist to the penicillins, cepheims, aminoglycosides, tetracyclines, and macrolides. Penicillin and its derivatives are the antibiotics of choice for terminating leptospiremia (Table 44-7), but they do not eliminate the carrier state. Initially, penicillin or ampicillin can be given parenterally to the vomiting, uremic, or hepatically compromised animal. Once oral alimentation is begun, oral therapy with amoxicillin is recommended because of its superior absorption. Other

Infectious Diseases of the Dog and Cat, 3rd Edition

drugs such as the tetracyclines, aminoglycosides, or macrolides should be provided after therapy with the penicillins and after oral alimentation is possible to eliminate the carrier state. Doxycycline can be used for initial therapy or for elimination of the carrier state. It can be given IV or by mouth, depending on the animal's state of alimentation. The dose does not need to be adjusted in animals with renal failure because doxycycline is predominantly excreted in the feces. Aminoglycosides, although highly effective in clearing the renal carrier state, should never be given to clear the carrier state unless results of renal function tests have returned to reference ranges. Streptomycin is less available and it has been replaced, in treatment of people, by gentamicin, tobramycin, and isepamicin.¹⁰⁴ In experimental studies in animals, ampicillin and first-generation cephalosporins have not been effective in eliminating the organisms from tissues and body fluids, whereas tetracyclines and macrolides such as erythromycin and its derivatives (clarithromycin, azithromycin) were effective.⁷ Third-generation cephalosporins, such as ceftiofur, have cleared the renal carrier state in cattle.⁸ Ceftriaxone, which is often used to treat human borreliosis, was as efficacious in treating severe leptospirosis in people.¹⁴⁸ Ineffective drugs include chloramphenicol and sulfonamides. Ciprofloxacin is effective in vitro and in vivo against virulent strains of leptospire, but its clinical application has been limited.¹⁸⁴ Orbifloxacin at recommended dosages was not effective compared with oral amoxicillin in treating one dog,⁷¹ and quinolones have not been effective in clearing experimentally infected animals.¹⁹⁹

414

415

Table 44-7 Recommended Therapy for Leptospirosis

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Penicillin G	B	25,000–40,000 units/kg	IM, SC, IV	12	2
Ampicillin	B	22 mg/kg	PO, SC, IV	6–8	2
Amoxicillin	D	22 mg/kg	PO	8–12	2
Doxycycline ^c	D	5 mg/kg	PO, IV	12	2
Tetracycline ^d	B	22 mg/kg	PO	8	2
Azithromycin ^e	D	20 mg/kg	PO	24	1

B, Dog and cat; D, dog; IM, Intramuscular; SC, subcutaneous; IV, intravenous; PO, by mouth.

- a Refer to [Appendix 8](#) for additional information on these drugs.
- b Dose per administration at specified interval.
- c Can be used as primary therapy or to clear renal carriers since excretion not affected by azotemia.
- d Used to clear the renal carrier once azotemia has resolved. Repositol oxytetracycline (LA-200) has been used to treat large numbers of affected foxhounds at an IM dose of 20 mg/kg once weekly for 4 weeks.
- e Efficacy of macrolides has not been well studied although they have an appropriate in vitro spectrum. Other alternatives are erythromycin or clarithromycin.

44.8 PREVENTION

Prevention of leptospirosis involves elimination of the carrier state. Unfortunately, wild animal reservoirs and subclinically affected domestic animals continue to harbor and shed organisms. Control of rodents in kennels, maintenance of environmental conditions to discourage bacterial survival, and isolation of infected animals therefore are important to prevent spread of the disease. Doxycycline has been given at a low dose (200 mg once weekly) to people in endemic areas for prophylaxis when vaccination with appropriate serovars is unavailable. Use at this lower level does not prevent infection but helps reduce morbidity and mortality in people who become

Infectious Diseases of the Dog and Cat, 3rd Edition

infected.¹⁷⁹ Such therapy may result in development of bacterial resistance and is not generally recommended for people or their pets.

Bacterins that contain four main serovars—canicola, icterohaemorrhagiae, grippityphosa, and pomona—are available for dogs. Some preparations contain only grippityphosa and pomona; others contain only canicola and icterohaemorrhagiae. Current vaccines are not completely cross-protective against other significant disease-causing serogroups such as *Sejroe* and *Autumnalis*. Experimental studies have documented that the LPS antigens are responsible for homologous protection, whereas protein antigens give both homologous and some heterologous protection.¹⁹⁰ Many currently marketed vaccines are chemically inactivated whole cultures, which makes them relatively allergenic in comparison with the tissue culture lines of virus vaccines (see Postvaccinal Complications, [Chapter 100](#)). Immunization has been effective in reducing the prevalence and severity of canine leptospirosis. Previously, inactivated bacterins did not prevent the carrier state, which is associated with potential zoonotic risk. Newer vaccines marketed for dogs and other species have prevented renal colonization and shedding.³⁴ Protection against postinfection shedding, which varied among tested vaccines, was observed when dogs were challenged up to 7 weeks after the second of two doses of three commercial vaccines.¹⁰

Adequate initial immunization, employing many of the available products, takes up to two to three injections 2 to 3 weeks apart to produce immunity to challenge infection that will last at least 6 to 8 months. Challenge studies in dogs have shown some leptospiral vaccines provide some protection against challenge at 3, 27, and 56 weeks (see [Table 100-12A](#)).¹⁰² Protection was complete at 3 weeks, but some organisms may be isolated from the blood of some animals at 27 and 56 weeks, indicating some decline in sterile immune protection with time.

Vaccines have been produced from the outer envelope fraction of leptospires, which is the site of leptospiricidal activity of antibody and complement.¹²⁷ Antigenic material has been reduced by culture in a protein-free media; adjuvants have been removed, and up to five *Leptospira* serovars have been included in such vaccines. Maximal antibody titers have been produced in dogs within 2 weeks after a single vaccination, and dogs have been protected against infection and urinary shedding after challenge. Recombinant-produced outer surface immunogenic lipoproteins (LigA-m and LigB-m) have shown promising results in challenge studies in mice.^{105a}

Agglutination titers, which are predominantly IgM, do not increase to very high levels following vaccination. IgG titers, which are primarily responsible for protection, are produced for at least 1 year after the third vaccination in dogs. Because immunity wanes with time, and because highest titers are produced by multiple injections, yearly (and sometimes biannual) vaccinations should be given to dogs in endemic areas, and all dogs in highly endemic regions should receive at least three injections in their primary vaccination series. For further guidelines concerning leptospirosis vaccination, see [Chapter 100](#).

44.9 PUBLIC HEALTH CONSIDERATIONS

People acquire infection through occupational, recreational, or avocational activities. *Leptospira* require humid conditions for their survival, and infected dogs, as with other animals, may disseminate the organism through urination in drinking, bathing, or recreational water sources. Seasonal flooding has been a major risk factor in some outbreaks in developing countries. Flooding elevates the water table, saturates the soil with leptospires, prevents evaporation of contaminating animal urine, and prolongs the survival of the spirochetes in surface water. The majority of infections in people are among those who experience occupational exposure to infected wildlife or domestic animal hosts, or engage in water sports activities, or contact animal urine or contaminated fomites in their daily lives.* Veterinary students have been documented to become infected during their course of training during the clinical years in the areas of food inspection, farm work, and contact with pet carnivores and animal

415

416

Infectious Diseases of the Dog and Cat, 3rd Edition

traders.¹⁸⁶ A few outbreaks have been associated with eating food contaminated with rodent urine.¹⁰⁴ Exposure to outdoor water-related activities have been a concerned risk for infection; however, a high rate of infection of leptospirosis has been identified in inner cities.²⁷ Exposure of people living in unsanitary environments to rodent urine has been suspected. The chance that dogs might be involved has not been eliminated.

Table 44-8 Outbreaks of Leptospirosis in People Associated with Exposure to Dogs

LOCATION AND DATE	NUMBER AFFECTED	EXPOSURE SOURCE	PRESUMPTIVE SEROGROUP	INFECTING SEROVAR ISOLATED	REFERENCE
North Dakota, 1950	9	Infected family dog	Canicola	NI	85
Georgia, 1952	26	Swimming in creek; dogs suspected	Canicola	NI	211
Japan, 1953	114	Swimming in river; dogs suspected	Canicola	canicola	138
Texas, 1971	7	Pet dogs	Canicola	canicola	19
Portland, Oregon, 1972	9	Infected family dog	Autumnalis	fort bragg	64
St. Louis, Missouri, 1972	5	Infected pet dogs	Icterohaemorrhagiae	icterohaemorrhagiae	62
Morón, Cuba, 1986	6	Swimming in creek; dogs suspected	Canicola	NI	89
Barbados, 1988	1	Kennel dogs	Autumnalis	bim	60
Nicaragua, 1995	100	Flooding, walking in creek; dogs suspected	Canicola	portlandvere	198, 216
NI, Not isolated.					

In some outbreaks, simultaneous exposure of people and dogs can occur (Table 44-8).²⁰² Contaminated urine is highly infectious for people and for susceptible animal species; therefore contact on mucous membranes or skin abrasions should be avoided. Spirochetes do not penetrate intact skin; however, open skin wounds, or softening or maceration of the skin from prolonged immersion in water, or exposure to mucous membranes, or swallowing water, greatly increases the risk of infection.^{77,153}

During treatment of animals suspected to be infected, precautions should be taken. The animals should be physically separated to prevent inadvertent contact with other animals or people. Latex gloves should be worn when handling urine or urine-contaminated items from animals. Facemasks and goggles should be worn when hosing contaminated kennel areas. Canine infection and leptospirosis have been found in healthy vaccinated dogs with resultant development of the disease in people. All known or suspected shedders should be treated with antibiotics. Once appropriate antimicrobial therapy has been instituted to affected animals, the public health risk is minimized because viable organisms will not be actively shed. Reshedding can occur when antimicrobial therapy is discontinued if drugs used to clear the renal carrier state are not used. Areas contaminated by infected urine should be washed with detergent and then treated with iodophor disinfectants (see Chapter 94) to which the organism is very susceptible. People with human immunodeficiency virus (HIV) are at particular risk for severe infection⁹⁷; therefore if they live in an endemic area, their dogs should be screened serologically for exposure and possible infection, and thereafter these animals should receive multivalent vaccination on a periodic basis. Chemoprophylaxis with tetracyclines has been used to prevent infection in people temporarily exposed to high-risk environments.

45 CHAPTER 45 Borreliosis

Craig E. Greene

Reinhard K. Straubinger

Members of the genus *Borrelia*, which contains at least 37 species, are usually categorized into one of two groups: the relapsing-fever borreliae or the Lyme borreliosis borreliae. Both groups contain pathogenic species and other borreliae that have been isolated only from ticks or asymptomatic animals. Lyme borreliosis is the most commonly diagnosed vectorborne disease in people. It has been reported in North America, Europe, and Asia. Unconfirmed accounts of the disease have come from Australia, South America, and Africa. This disease is one of a larger group of vectorborne borrelioses that affect mammalian and avian hosts (Table 45-1). Experimentally and spontaneously induced Lyme borreliosis has been described in dogs, cats, and other animals. Because of the difficulty in confirming a diagnosis and the diversity of borrelial species being isolated from ticks, controversy still exists regarding the exact prevalence and geographic distribution of infection. The relapsing-fever borreliae affect people and domestic animals. Only one confirmed case in which these organisms were isolated from clinically ill dogs has been reported.²⁵ The discussion that follows focuses on Lyme borreliosis (about which more information is available) unless otherwise indicated.

45.1 ETIOLOGY

45.1.1 Lyme Borreliosis

Like most spirochetes, borreliae are small ($0.2 \times 30 \mu\text{m}$), and dark-field or phase microscopy is needed for proper visualization of live organisms (Fig. 45-1). The genospecies of *Borrelia burgdorferi* sensu lato, the causative agent of Lyme borreliosis, has been divided into at least four genomic species groups (see Table 45-1).^{35,66} Analysis of outer surface proteins (Osps) such as the lipoproteins OspA and OspB and of genetic and amino acid sequences have been used to subgroup the *Borrelia* species. Group 1 (*B. burgdorferi* sensu stricto) is the primary isolate seen in the United States. In people, it is associated with annular skin lesions, polyarthrititis, and meningitis. In the United States, *Borrelia andersonii* and *Borrelia bissettii* have been isolated from *Ixodes* ticks on rabbits or rodents and birds, respectively; their pathogenic significance is uncertain. In Europe, groups 1, 2, and 3 have been isolated from people, with groups 2 (*Borrelia garinii*) and 3 (*Borrelia afzelii*) predominating. In most European countries, *B. garinii* is the most abundant species being isolated from *Ixodes ricinus* ticks.²¹² The three main *Borrelia* genospecies in Europe appear to have common rodent hosts, and many of these hosts harbor multiple infectious agents.²⁰⁷ The greater diversity among species in Europe suggests that this complex of organisms originated in Eurasia.²⁶² However, other evidence suggests that *B. burgdorferi* sensu stricto may have been reintroduced into Europe from transported mammalian hosts. *Borrelia valaisiana* has been isolated from *I. ricinus* ticks on vegetation and birds; however, its pathogenic significance if any is uncertain. Meningopolyneuritis (Bannwarth's syndrome) is the primary clinical sign in people with group 2 infection, whereas in Europe, group 3 seropositivity has been associated with chronic arthritis and dermatitis (erythema chronica migrans [ECM]).⁵⁷ *B. afzelii* has been isolated from a naturally infected dog,²³⁸ and mixed infections with this and other European species has been described.²³⁸ A new species, *Borrelia japonica* (group 4), has been isolated from ticks found on dogs and people in Japan.⁹ In the same region two additional species, *Borrelia takunii* and *Borrelia turdi*, have been isolated from ticks from small mammals; however, their pathogenic significance is uncertain. In the northeastern United States, *B. andersonii* has been

Infectious Diseases of the Dog and Cat, 3rd Edition

found in ticks from rabbits. In the southeastern United States, more than 200 *Borrelia* strains have been isolated that can be classified molecularly into *B. burgdorferi* sensu stricto.¹⁸⁸ They feed on principal small mammal reservoirs such as the cotton mouse, the cotton rat, the eastern wood rat, and the cottontail rabbit. Other yet unidentified pathogenic and nonpathogenic strains of *Borrelia* exist.¹⁶⁹ A variant *Borrelia* species has been associated with ECM skin lesions in people in Missouri.¹⁶⁴ Southern tick-associated rash illness (STARI) is a Lyme borreliosis-like illness that occurs in people in the southeastern and south central United States, and the organism *Borrelia lonestari* has been cultured from these individuals.²⁵⁷ The differences in strains or species may account for the regional differences in clinical findings that have been reported.

On the basis of in vitro borreliacidal assays, North American and European isolates of *B. burgdorferi* are divided into at least five seroprotective groups that differ from the species groups previously described.¹⁴⁹ Although North American isolates have been thought to be more homogeneous than European strains, isolates from the United States have substantial genetic heterogeneity with regional differences.¹⁶⁶

(Courtesy R. Straubinger, University of Leipzig, Leipzig, Germany.)

45.1.2 Relapsing-Fever Borreliosis

Numerous borreliae species comprise the relapsing-fever group of vectorborne agents that cause disease in domestic animals and people (see [Table 45-1](#)). Except for *Borrelia recurrentis*, which causes louseborne relapsing fever, all are transmitted by ticks. The occurrence of most of these infections in dogs and cats have not been substantiated. A previously unrecognized borrelial species was described in dogs from Florida; spirochetemia was visible.²⁵

45.2 EPIDEMIOLOGY

45.2.1 Lyme Borreliosis

Unlike *Leptospira* organisms, borreliae cannot survive as free-living organisms in the environment. They are host associated, being transmitted between vertebrate reservoir hosts and hematophagous arthropod vectors. *B. burgdorferi* sensu lato infections are geographically dispersed (see [Table 45-1](#)). In general, Lyme borreliosis occurs in temperate latitudes with cooler climatic conditions. In the United States, it has been reported in people

Infectious Diseases of the Dog and Cat, 3rd Edition

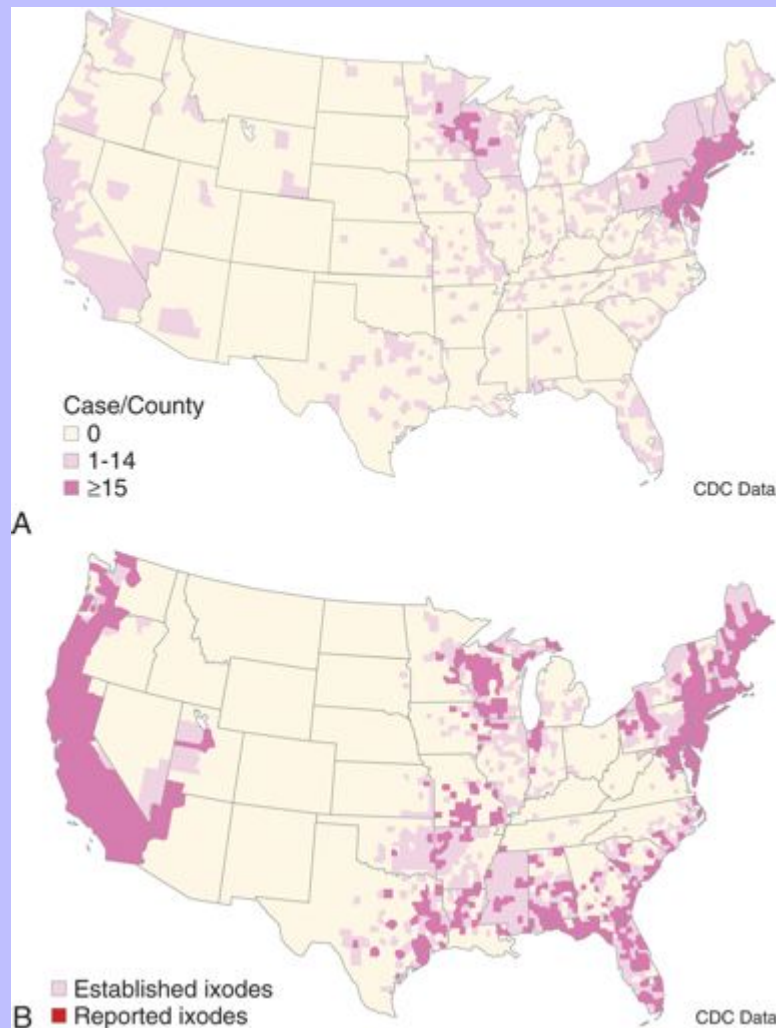

in 50 states; however, approximately 85% of the cases were from eastern coastal states from Massachusetts to Virginia, 10% were from the upper Midwest (Wisconsin and Minnesota), and 4% were from northern California (Fig. 45-2, A). Although 1% of the reports were from other states, the organism has never been cultured from people or dogs outside the mentioned endemic areas. In Canada, Lyme borreliosis is endemic in southeastern Ontario. Less is known about the national seroprevalence of canine infection or exposure.

The principal vectors of *B. burgdorferi* sensu lato are various species of slow-feeding hard ticks of the *Ixodes* complex, whose distribution is associated with the prevalence of disease (Table 45-2). In the United States, closely related black-legged ticks, *Ixodes scapularis* (in the northeastern, midwestern, and southeastern states) and *Ixodes pacificus* together with *Ixodes neotomae* (in the western states)²⁷ appear to be involved (Fig. 45-2, B). Differences in the northern and southern populations of *I. scapularis* influence the prevalence of disease in these respective areas. *I. scapularis* in the northeastern states was previously designated “*Ixodes dammini*.” Debate continues over whether it is distinct from *I. scapularis*. Ticks in the north central United States prefer deciduous, dry to mesic forests and sandy or loamy soils overlying sedimentary rock.⁹⁵ Ticks were not associated with grasslands, conifer forests, or acidic soils with low fertility or a claylike consistency.

These small (less than 3 mm) ixodid ticks generally feed on more than one host during their life cycle (Fig. 45-3). The number of hosts varies depending on the tick species. In North America, where approximately 50 to 80 vertebrate species are hosts, larvae and nymphs of *I. scapularis* (the northern variety) generally feed on small mammals, whereas *I. scapularis* (the southern variety) and *I. pacificus* feed on reptiles. Adults of these ticks feed on deer or larger mammals. Because reptiles are not competent reservoir hosts, the infection rate of southern *I. scapularis* ticks (less than 1%) is much lower than that of northern *I. scapularis* ticks in the northeastern United States (10% to 50%). Lizards possess a borreliacidal substance similar to complement in their blood that reduces or prevents infection with *B. burgdorferi*.¹²⁹ Furthermore, because the southern *I. scapularis* ticks do not always feed on mammals, the prevalence of Lyme borreliosis in people and domestic animals is low in the southern regions.²⁶⁹ Infected *Ixodes* ticks may be dispersed to new areas by feeding on migratory birds.^{111,127,225,234}

419

Fig 45-2 **A**, Annual incidence in 2000 of Lyme borreliosis in the United States by county. Darker color indicates higher concentration of cases as indicated in the legend. **B**, Distribution of *Ixodes* species ticks in the United States by county. (Data from Centers for Disease Control and Prevention, Atlanta, Ga. Maps courtesy University of Georgia, Athens, Ga.)

I. ricinus and *Ixodes persulcatus* are the primary vectors in Europe and Eurasia, respectively. In Europe, most cases have been documented in the Scandinavian countries and in central Europe, especially in the Alpine countries of Germany, Austria, and Switzerland in association with *I. ricinus* (Fig. 45-4). *B. burgdorferi*, *B. garinii*, and *B. afzelii* are responsible for the infection. The distribution of infection stretches eastward across Eurasia, corresponding to the habitat of the tick *I. persulcatus*, which transmits only *B. garinii* and *B. afzelii*.

Infectious Diseases of the Dog and Cat, 3rd Edition

Infection with *B. burgdorferi* sensu lato, *B. burgdorferi* sensu stricto, and *B. garinii* has also been found in *I. ricinus* ticks in northern Africa.²¹⁴ Other isolated enzootic cycles exist in nature between *Ixodes* ticks and rodents infected with new *Borrelia* species.¹⁸² For example, *I. ricinus*-complex ticks have also been infected with the other genospecies, including *B. valaisiana*, *B. bissettii*, and *Borrelia lusitaniae*.²⁰⁹ In these cases, the infection is being maintained in nature; however, the clinical significance of such infections in people or domestic animals is unknown.

In Europe and Asia, *I. ricinus* and *I. persulcatus*, respectively, parasitize more than 200 vertebrate species. Several species of mice, voles, and rats are important reservoir hosts. Squirrels, hedgehogs, shrews, and birds are also involved in the maintenance of the infection cycle. On both continents, larger ungulates such as deer and moose are important in the life cycle because adult *Ixodes* species feed on them. However, the level of infection in these large mammals is insufficient to transmit to feeding ticks, making them unsuitable reservoir hosts.^{114,178,254}

The *Ixodes* species ticks that transmit Lyme borreliosis have a 2-year life cycle and maintain infection in nature by over-wintering as infected nymphs (see Fig. 45-3). In the northeastern and upper midwestern United States, *I. scapularis* primarily becomes infected when immature stages feed on infected white-footed mice (*Peromyscus leucopus*). Direct transmission of borreliae between reservoir hosts is unlikely, and transovarial transmission in ticks is relatively nonexistent.¹⁹⁶ When infected nymphs that have over-wintered feed in the spring, they transmit organisms to competent reservoir hosts. Nymphs are thought to be primarily responsible for the transmission of infection to domestic animals and people. The larvae from the current year's generation feed in late summer and fall off the host and become infected by feeding on an infected reservoir host.^{30a} Larvae and other stages of ticks can also become infected from previously uninfected hosts by cofeeding with infected ticks that have attached in close temporal and spatial proximity.^{185,205} However, in other studies, cofeeding of *I. ricinus* ticks was not as efficient in transmitting *B. afzelii* infection as horizontal transmission of the organism from previously infected mice to uninfected larvae.^{207,208} After molting, nymphs become infected and over-winter for the next tick season (see Fig. 45-3). Adult female ticks feed on white-tailed deer (*Odocoileus virginianus*) to maintain the tick population, but deer are not effective reservoir hosts for infection.¹¹⁴ Despite the zoonotic risk from nymphal ticks, adult ticks appear to have the highest rate of infectivity among stages, presumably because of their longevity and repeated exposure to infected mammals and birds.

In the western United States, transmission of infection by *I. pacificus* involves two sylvan cycles. The maintenance cycle involves *Ixodes spinipalpus* feeding on dusky-footed wood rats (*Neotoma fuscipes*) and kangaroo rats (*Dipodomys californicus*). Immature *I. pacificus* become infected by feeding on these rodent reservoirs, and the adult ticks transmit the infection to larger mammals during subsequent feedings. As in Europe, birds may be more important in the sylvatic cycle of infection in the western United States.²⁷⁰

Ixodes ticks can be simultaneously infected with additional animal and human pathogens, including *Rickettsia helvetica*, *Anaplasma phagocytophilum* (formerly classified as *Ehrlichia* species; see Chapter 28 and Table 28-1), *Babesia* species (*Babesia microti*, *Babesia odocoilei*, and *Babesia gibsoni*), and multiple *Borrelia* species.^{107,175} *Amblyomma americanum* (the Lone Star tick) can be coinfecting with *B. lonestari*, *Ehrlichia ewingii*, and *Ehrlichia chaffeensis*. Diagnosis and interpretation of serologic tests is problematic when a coinfection exists.

Infectious Diseases of the Dog and Cat, 3rd Edition

Numerous hematophagous arthropods, including other tick species, fleas, flies, and mosquitoes, have been found to be infected in nature. Whether these infections indicate vector competency is uncertain, but their role relative to ticks is insignificant. Contamination from feeding on infected vertebrates is suspected; however, these other arthropods have not been documented to transfer infection to new hosts.²⁰¹ Only *I. scapularis*—not *A. americanum* or *Dermacentor variabilis*—has effectively transmitted a diverse collection of *B. burgdorferi* strains from North America.²⁰¹ Nevertheless, *A. americanum* has been found to harbor *B. lonestari*, a presumptive species that causes an ECM-like rash in people and may be associated with seropositivity in people and animals in areas where *Ixodes* species ticks are not found.²²⁶ Experimentally, deer but not mice were infected with *B. lonestari*, and organisms were observed in Giemsa-stained blood smears.¹⁴⁶ Deer may be reservoir species for this organism.

Contrary to media reports, Lyme borreliosis is not spreading in epidemic proportions; it is likely being overdiagnosed by use of nonspecific serologic testing. Nevertheless, it is a significant disease problem in the geographic regions in which it occurs. Although the disease in Connecticut was first recognized in 1975, evidence suggests that *B. burgdorferi* has infected indigenous wildlife and their respective tick vectors for many years. Studies have demonstrated that ear skin samples from museum specimens of the white-footed mouse collected near Dennis, Massachusetts, during 1894 contained *B. burgdorferi* DNA.¹⁶² Similarly, embalmed ticks collected from Long Island, New York, from the 1940s¹⁹⁹ and from Europe dating back to the 1880s¹⁶⁸ have also been found to contain borrelial genetic material.¹¹⁰ The disease has been recognized in Europe since the beginning of the twentieth century.

420

422

Table 45-2 Selected Vectors of *Borrelia burgdorferi*^a

SPECIES	GEOGRAPHIC LOCATION	FEEDING PREFERENCE		
		LARVAE, NYMPH	ADULTS	INFECTION PREVALENCE
Northern <i>Ixodes scapularis</i> (previously <i>Ixodes dammini</i>)	United States (New England, northern Midwest)	White-footed mouse (<i>Peromyscus leucopus</i>), small mammals, birds	Deer, larger mammals	<1% larvae 10%–25% nymphs 10%–50% adults
Southern <i>I. scapularis</i>	United States (southeastern)	Lizards	Lizards (occasionally mammals)	<1% larvae <1% nymphs <1% adults
<i>Ixodes pacificus</i> , <i>Ixodes neotomae</i>	United States (western)	Lizards	Lizards (occasionally mammals)	1%–5%
<i>Ixodes ricinus</i>	Europe (western and central)	Small mammals, birds, mice (<i>Apodemus flavicollis</i> , <i>Apodemus sylvaticus</i> , <i>Clethrionomys glareolus</i>)	Deer, larger mammals	10%–25%
<i>Ixodes persulcatus</i>	Eurasia, Soviet Republics	Small mammals, birds	Deer, larger mammals	10%–25%

^a *B. burgdorferi* or related organisms have been recovered from numerous other ticks and arthropods in nature, but the significance is uncertain. Many sylvan cycles exist in nature in which tick vectors

Infectious Diseases of the Dog and Cat, 3rd Edition

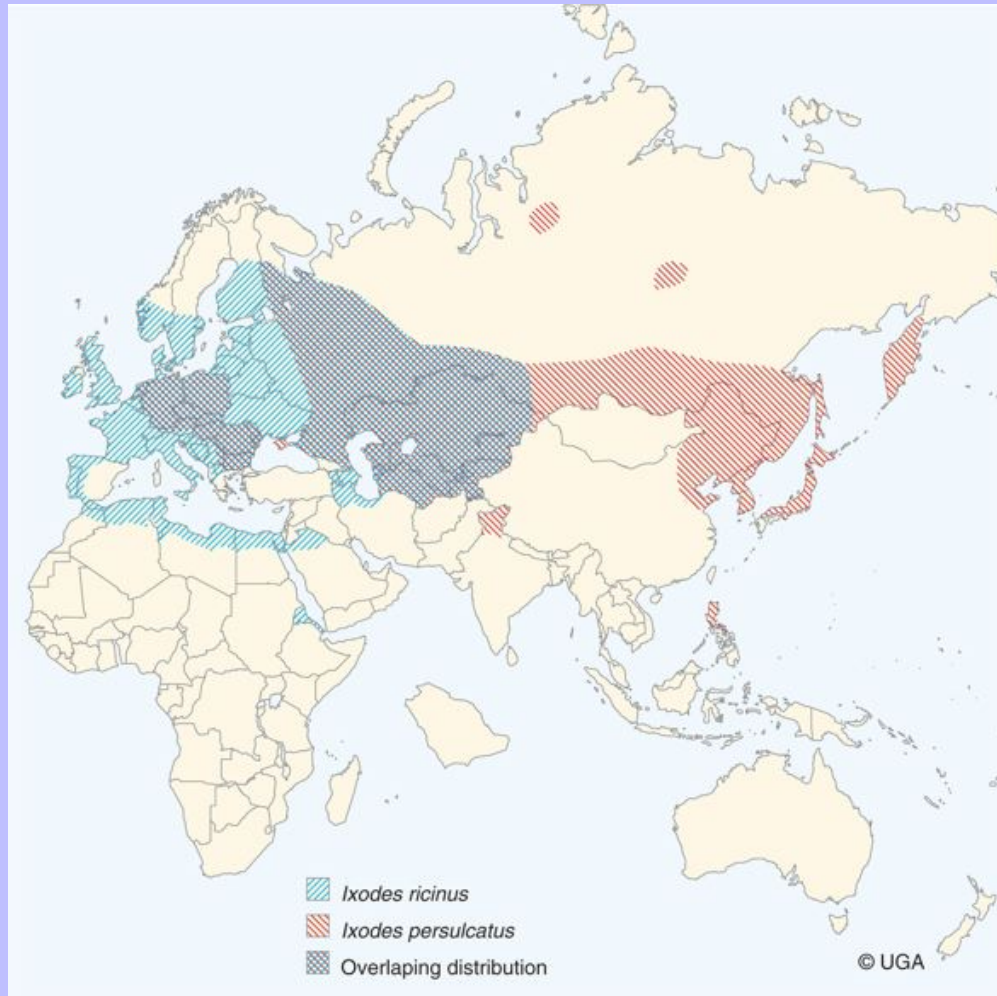

do not feed on large mammals. Only the established vectors for people or domestic animals are listed here.

Fig 45-3 The life cycle of northern *I. scapularis* (“dammini”) lasts 2 years. Eggs are oviposited in the spring, and the larvae emerge approximately 1 month later. They feed once in the summer, usually on birds and small mammals, and then over-winter. The following spring, the larvae molt into nymphs, which then feed in late spring or early summer. The nymphs feed on mice or larger mammals such as dogs, deer, or humans and are considered the most likely source of infection for dogs and people. Nymphs then molt into adults in the fall. The adults usually feed on larger mammals (often the white-tailed deer), where they mate. The females die after laying their eggs, and the 2-year cycle is repeated. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 45-4 Distribution of *I. ricinus* and *I. persulcatus* ticks in the Eastern Hemisphere. Distribution of Lyme borreliosis follows this geographic range. (Courtesy University of Georgia, Athens, Ga.)

Despite the long-standing presence of the borreliac sylvan cycle, certain environmental conditions probably caused Lyme borreliosis to become more prevalent in people in the twentieth century. Before 1900 the habitat of the eastern United States was heavily deforested by early settlers. Populations of deer and their associated ticks, such as *I. scapularis*, were reduced. During this time, a sylvan cycle maintaining *B. burgdorferi* most likely existed between *Ixodes muris*, a one-host tick, and rodent species, which were most prevalent in forest-free areas. After the turn of the century, farms were abandoned and reforestation occurred, as did a continual increase in the deer population. With an increase in deer numbers came a corresponding increase in black-legged ticks. As the numbers of infected ticks of these species increased, the likelihood that people and domestic animals would come in contact with infected ticks also increased. Although Lyme borreliosis is generally associated with forests, it may be acquired in parks in major metropolitan centers. In these areas, rats

Infectious Diseases of the Dog and Cat, 3rd Edition

appear to be the effective reservoir host for feeding ticks.^{167,235} In the northern midwestern United States, seropositivity among dogs was positively associated with numerous risk factors including increased tick exposure, time spent outdoors, and living in forested or urban wooded habitats and on sandy, fertile soils.⁹⁷ Larval and nymphal *Ixodes* are found in moist, protected areas such as under humus on the floor of hardwood forests. They feed on small rodents, lizards, and ground-feeding birds. The adult ticks climb onto tips of grasses or vegetation to quest and wait for larger mammals to contact them. In the United States, *Ixodes* species ticks are distributed in wooded regions adjacent to the Atlantic Coast, lake regions of the Midwest, and Pacific coastal ranges. These regions have high humidity and more temperate climates moderated by the abundant adjacent bodies of water.

No evidence proves that infected pet dogs or cats pose a direct risk to people other than that they introduce unfed ticks in various life cycle stages into a household. The ticks do not survive long indoors and if fed, they do not reattach without molting. However, partially fed ticks can pose a greater risk of infection to the second mammalian host because a shorter period of attachment is required to transmit infection to the second host. *Ixodes* ticks are extremely small and detected in only a low percentage of cases of Lyme borreliosis (Fig. 45-5). Unfortunately, pets may be blamed for a human infection when ticks are actually the source of the infection. Experimentally, dogs that became infected with *B. burgdorferi* after exposure to infected adult ticks were able to transmit infection to feeding immature ticks.¹⁶⁵ Therefore dogs could increase the human risk of exposure by serving as competent reservoirs of infection for ticks, although dogs are not the preferred hosts for these ticks.

Fig 45-5 Northern *I. scapularis* ("dammini") is smaller than other ticks commonly found on dogs. From largest to smallest, two adults (male, female), two nymphs, two larvae (bar = 1 mm). (Courtesy Mike DeRosa, West Somerville, Mass.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Direct horizontal spread from dogs and cats to people is unlikely; pets merely serve as sentinels for human infection. Most contact studies in which horizontal transmission occurred in dogs have been performed by exposure coincident to the time of parenteral inoculation.⁴⁰ Pregnant bitches were inoculated parenterally every 2 weeks during pregnancy induced by artificial insemination (AI) of semen from infected male dogs.⁹⁸ Infection in the offspring was determined by polymerase chain reaction (PCR) detection of DNA sequences. A majority of the females had at least one infected neonate when the pups were tested up to 6 weeks of age. The presence of IgM antibodies in a pup that did not nurse suggested that the infection occurred in utero. However, infection by parenteral inoculation may have superseded the uterine-placental barrier.

In a more natural infection model study with ticks, control dogs that were in direct contact with infected dogs for up to 1 year did not undergo seroconversion, and organisms could not be isolated from the urine or urinary bladder of infected dogs.⁶ Canine urine is an unlikely source of infection. These investigations also could not document any evidence of in utero spread despite seroconversion of the dam. *B. burgdorferi* can survive freezing and storage, making semen intended for AI a potential source of infection.¹²⁶ Blood transfusions could be another source of infection for dogs and cats. *B. burgdorferi* organisms can survive in blood processed for transfusion and stored under blood-bank conditions.^{116,177} However, not a single case of *B. burgdorferi* infection caused by blood transfusion has been documented in people^{74,21} or animals, and no animal model exist in which Lyme borreliosis can be induced by intravenous (IV) injection of *B. burgdorferi* organisms.

45.2.2 Relapsing-Fever Borreliosis

Relapsing fever is a typical zoonotic disease in which the pathogen is maintained in nature between susceptible reservoir hosts and competent soft ticks. Because of the susceptibility of soft ticks to the environment, their reservoir hosts are a variety of burrow-inhabiting mammals. In contrast to Lyme borreliosis, a wide variety of vertebrates such as rodents, lagomorphs, and ungulates can serve as hosts for the ticks. Despite this fact the borreliae causing relapsing fevers have more restricted geographic ranges and niche vectors than those causing Lyme borreliosis (see [Table 45-1](#)). In the western United States and Mexico, *Ornithodoros turicata* infests burrows of rodents, terrapins, and snakes, as well as domestic habitats of people and animals. In the western United States, *Ornithodoros hermsi* and *Ornithodoros parkeri* feed on rodents and squirrels and live in dead trees, fallen logs, and cabins and homes. Tickborne relapsing fever in the United States has not been reported in states east of Texas and Oklahoma; however, sporadic isolations have been made from ticks and people outside this area. Relapsing-fever—like borreliae have been isolated from *Ornithodoros erraticus*, an important vector in northern Africa that feeds on rats, mice, gerbils, and other small mammals. *Ornithodoros tholozani* inhabits the Middle East, the Balkans, and the southern former Soviet Republic, where it inhabits man-made shelters and caves while feeding on various wild and domestic animal hosts and people. A relapsing-fever—like spirochete, *Borrelia miyamotoi*, has been isolated from *I. persulcatus* ticks in Japan.⁷⁰ New relapsing-fever borreliae have been identified in North American *I. scapularis* ticks²²⁴ and European *I. ricinus* ticks.²⁰⁹ The clinical significance of these infections in people and animals is unknown.

45.3 PATHOGENESIS

45.3.1 Lyme Borreliosis

Spirochete transmission requires at least 50 hours⁵¹ of tick attachment, during which time organisms multiply and cross the gut epithelium into the hemolymph, disseminate to the salivary glands, and infect the host through

Infectious Diseases of the Dog and Cat, 3rd Edition

tick saliva.¹⁹⁵ OspA, the predominant surface protein, is expressed on the outer surface of borreliae in the midgut of infected nymphal ticks. In unfed ticks, virtually all spirochetes reside in the midgut. OspA has been shown to help the spirochetes adhere to midgut epithelial cells. During feeding and because of the warmth and ingested blood meal, spirochetes down-regulate their expression of OspA protein and express OspC. The up-regulation of OspC correlates with the migration of the spirochetes from the midgut into the hemolymph and finally to the salivary glands of the feeding tick.¹⁹⁵ OspC facilitates the adherence of spirochetes to the tick salivary gland cells and likely to host tissues as well. Levels of the immunodominant lipoprotein component VlsE, which is important in serodiagnosis, increase during the last 2 days of tick engorgement.²⁰² Sufficient numbers of virulent spirochetes are not present in the salivary glands until approximately 53 hours have elapsed.¹⁸⁷

Despite the numerous people and animals that are bitten, only a few develop clinical disease. Host immune reactions are likely involved in preventing many of these infections. From the vector perspective, up to 50% (see Table 45-2) of *Ixodes* ticks may be infected in endemic regions, whereas less than 2% of people bitten by these ticks become infected. The implication is that most ticks are removed before this patent period.

423

As the number of attached ticks and correspondingly the number of inoculated spirochetes increase, the likelihood increases that clinical illness will result; host immunity is important in this regard. It is likely that borreliae proliferate locally in skin at the site of tick attachment and spirochete inoculation for the duration of infection. From there, they replicate and migrate through tissues, beginning close to the tick bite. Later, they can spread through and infect many tissues, including the joints. Active migration in tissues is more common than passive dissemination via the blood. Not all animals infected after tick bites develop clinical illness. In fact, evidence suggests that the percentage of dogs developing clinical disease is very low (5% to 10%) compared with the frequency of exposure based on seropositivity (75% in endemic areas) and the rate of infection demonstrated in ticks.¹⁴⁰ Part of this seropositivity may represent an exposure to infectious but nonpathogenic isolates of *Borrelia* in addition to indicating infection with low numbers of *B. burgdorferi* organisms in a host with an efficient immune system.² Even among genetically similar *B. burgdorferi* sensu stricto strains, pathogenicity may vary. Development of disease in genetically identical susceptible mice was determined by the pathogenic properties of the infecting *B. burgdorferi* isolate.²⁶¹

424

Once in the body, *B. burgdorferi* acts as a persistent pathogen. Experimental evidence suggests the spirochetes exist extracellularly and in an undetermined way can evade immune clearance for extended periods in the skin, connective tissues, joints, and nervous system. Data suggest that these spirochetes undergo major changes in surface protein expression as they enter the host.⁴⁹ Other studies have shown that *Borrelia* organisms are capable of modifying not only their outer surface profile but also their entire shape. Spiral, motile borreliae can change into spherical life forms within minutes after they have encountered unfavorable environmental conditions (Fig. 45-6).^{1,26} In this form they survive for days without nutrition and revert back into the well-known spiral form when conditions improve. Furthermore, these spherical borreliae were able to infect mice.⁹⁴ This may explain the reason *B. burgdorferi* can still persist and be detected in tissue samples by PCR or occasionally by culture even after months of antibiotic treatment. After a few weeks of infection, *B. burgdorferi* is difficult to detect or isolate from body fluids or internal organs of incidental hosts such as dogs, and exceedingly few are detected in other tissues.^{6,45,82} Clinical illness results from the host's own inflammatory response. Some of the immunopathologic events may be related to immune responses generated against specific borrelial antigens. Flagellin, one of the most immunogenic proteins, can elicit an antibody that binds to host neuroaxonal proteins.²³⁰ This sequence may in turn stimulate the inflammatory response in nervous tissue.²³¹

Clonal accumulation of activated CD8⁺ T cells has been observed in the cerebrospinal fluid (CSF) of people

Infectious Diseases of the Dog and Cat, 3rd Edition

during the early phase of neuroborreliosis.¹¹² The cytokine release may help the inflammatory response clear the organism but also results in damage to nervous tissue. Results of PCR on synovial fluid are often positive in human patients, because genetic sequences for plasmid-encoded genes such as *OspA*, *OspB*, and *OspC* are readily detected¹⁹⁸; results of culture studies are usually negative.¹⁹⁸ The inflammatory response to a small number of spirochetes may be explained by autonomous replications of plasmid DNA.²⁶⁶ Up-regulation of interleukin-8 (IL-8), which recruits neutrophils to inflammatory sites, has been found in the synovial membranes of experimentally infected dogs.²⁴⁸ This may be an important mechanism in producing suppurative polyarthritis. In a few animals the development of arthritis is probably related to pathologic perpetual host immune reactions. People with certain haplotypes of the major histocompatibility complex are prone to more severe, treatment-resistant clinical manifestations of the disease in which *B. burgdorferi* cannot be detected.²⁴⁰

Fig 45-6 A, Transmission electron microscopic ($\times 12,000$) and **B**, scanning electron microscopic ($\times 12,000$) appearance of cystic form of *B. burgdorferi*, a defense mechanism of organism for survival under adverse conditions such as antimicrobial therapy or host immune defenses. (Courtesy R. Straubinger, University of Leipzig, Leipzig, Germany.)

The tissues of preferential localization may vary by *Borrelia* species, affect pathogenicity, and therefore determine the difference in clinical manifestations seen in different geographic regions. *B. garinii* was found in the liver of dogs having elevated liver enzyme activities, a finding not associated with *B. burgdorferi* sensu stricto.¹⁰⁹

The Jarisch-Herxheimer reaction (JHR) is a severe systemic reaction that is observed after receiving antimicrobial therapy for spirochetal or other bacterial infections. It is associated with the systemic release of cytokines (e.g., tumor necrosis factor- α [TNF- α], IL-6, and IL-8). The JHR has many similarities to severe sepsis. Clinical signs include fever, rapid pulse and respiration rates, an increasing blood pressure, and leukopenia. Pretreatment with antibodies against TNF- α keeps the JHR from developing in people.⁶⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

45.3.2 Relapsing-Fever Borreliosis

Tickborne relapsing fever, caused by *Borrelia hermsii* and transmitted by *O. hermsi*, is the model spirochetal disease of the relapsing-fever group. The principal mammalian reservoirs for this infection are diurnal rodents; people and other animals become infected as incidental hosts. Unlike the *Ixodes* species, *Ornithodoros* ticks harbor spirochetes for extended periods because their life cycle takes years to complete. Mammalian hosts are only intermittently spirochetemic for 14 to 30 days, thus the ticks are most responsible for maintaining the infection in nature. Unlike other *Ornithodoros* species, *O. hermsii* does not excrete coxal fluid while feeding; it must transmit the organism while biting the host. Whereas the organisms in *B. burgdorferi*-infected *Ixodes* ticks migrate from the midgut to the saliva, the salivary gland, midgut, and other tissues of *O. hermsii* are permanently contaminated with *B. hermsi* organisms, which allows for rapid transfer of the spirochetes. Furthermore, argasid ticks feed and transfer infection more rapidly than ixodid ticks and can immediately infect the host during the short tick-feeding interval.

In the mammalian host, *B. hermsii* has been shown to be highly adapted and has developed mechanisms to evade the immune system. Each inoculated spirochete may produce 30 unique antigenic variants, each expressing a major immunodominant protein that defines a specific serotype. In the mammalian host, episodes of cyclic spirochetemia are caused by waves of replicating spirochetes with relatively homogenous serotypes. As each new wave of replication becomes recognized by the host defenses, a new one is expressed, allowing the subsequent generation to proliferate—hence the relapsing nature of infection. Analyses of the surface proteins of *B. hermsii* have shown that the organism expresses a variable major protein, Vsp 33; however, after ingestion by the tick, a new major protein is up-regulated on the cell surface and confers the unique specific serotype. The Vsp 33 protein is homologous to the OspC protein of *B. burgdorferi* and as a result allows the organism to maintain its infectivity within the nonfeeding tick.

45.4 CLINICAL SIGNS

45.4.1 Lyme Borreliosis

The clinical features of Lyme borreliosis in people include dermatitis, arthritis, meningoencephalitis, and myocarditis.

45.4.1.1 Dogs

Initial attempts to recreate experimental Lyme borreliosis in dogs using laboratory-derived strains were unsuccessful, as they were in cats.^{31,89} However, fever and polyarthritis have been experimentally produced after inoculation or natural exposure to tick-derived *B. burgdorferi*.^{6,40,82,263} The use of spirochetes directly inoculated during feeding of field-collected ticks has been most successful.⁶ Clinical illness in experimentally infected dogs occurs 2 to 6 months after tick exposure, and the severity and propensity to develop signs of illness seem to vary inversely with the animal's age and immune status. The onset of clinical illness usually correlates with the initial increase in serum antibody titer.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 45-7 Experimentally induced borrelial arthritis in **(A)** thoracic limb of beagle dog and **(B)** pelvic limb of hound. Fever and shifting leg lameness develop 60 to 90 days after inoculation. Lameness occurs earliest and is most severe in limb closest to inoculation site. **A**, Courtesy R. Straubinger, University of Leipzig, Leipzig, Germany; **B**, Courtesy University of Georgia, Athens, Ga.)

45.4.1.1.1

Systemic Signs

Acute signs of fever (39.5°C to 40.5°C [103.1°F to 104.9°F]), shifting leg lameness, articular swelling, lymphadenomegaly, anorexia, and general malaise, all of which are responsive to antimicrobials, most commonly develop in naturally exposed seropositive dogs.^{136,140,145,170} The accuracy of the diagnosis in many spontaneously diseased dogs is difficult to determine because limb and joint signs (swelling, lameness, and pain) with fever and inappetence have been observed with equal frequency in dogs with and without *B. burgdorferi*-specific antibodies.^{44,156,155}

45.4.1.1.2

Arthritis

Polyarthrititis is the best experimentally documented syndrome caused by acute *B. burgdorferi* infection in dogs (Fig. 45-7). Spread of the organism in skin, connective, joint, and muscle tissues is most likely responsible for some of the observed lameness. The first limbs affected are usually closest to the site of tick attachment. The onset of lameness can correspond to an increased body temperature. Lameness in a particular limb often lasts for a few days and then may shift to another limb or disappear. Despite the transient nature of the arthritis, pathologic changes in the joints are progressive. Chronic nonerosive polyarthrititis, the primary condition found in more animals with prolonged infections than in untreated patients, may persist despite antimicrobial therapy at a lower frequency. Lesions have been most consistently found in skin, lymphatic tissues, and joints, even though the organism can be isolated from other tissues and body fluids.

Infectious Diseases of the Dog and Cat, 3rd Edition

45.4.1.1.3

Renal Disease

Protein-losing glomerulopathy has been described in a few naturally infected dogs.^{81,172} An acute progressive renal failure associated with azotemia, uremia, proteinuria, peripheral edema, and body cavity effusions has been characterized in 49 dogs from *Borrelia*-endemic areas.⁴⁶ A preponderance of Labrador and golden retrievers was affected. The duration of clinical illness was 24 hours to 8 weeks, with a sudden onset of anorexia, vomiting, lethargy, and weight loss. Some dogs had recent or concurrent lameness. All dogs died or were euthanized as a result of renal failure. The dogs had antibodies to *B. burgdorferi*. Natural exposure to *B. burgdorferi* was likely involved but has not yet been proven. In rapidly progressing glomerular disease, the role if any of vaccination in the development of the lesion is undetermined.

45.4.1.1.4

Meningitis

Often a later manifestation of lyme borreliosis infection in people is neurologic signs. Experimental infections of nonhuman primates have produced similar features.²¹⁰ The rhesus monkey is the only animal model to exhibit this predominant form of Lyme borreliosis. Experimentally infected dogs developed mild focal meningitis, encephalitis, and perineuritis; however, neurologic signs were not observed.⁴²

45.4.1.1.5

Other Manifestations

A small, reddish lesion develops in the skin at the site of tick attachment but disappears within the first week (Fig. 45-8). However, the organism can be isolated from the skin for extended periods. This lesion is not like the dramatic lesion associated with ECM in people. Erythematous rashes, suggestive of early Lyme borreliosis, may not be specific for this disease. In the southern United States, focal rashes (Fig. 45-9) and transient fever and malaise associated with the bite of *A. americanum* ticks were attributed to infection with *B. lonestari*, an organism more closely related to *Borrelia miyamotoi*, a relapsing-fever spirochete in Japan, and the unnamed species isolated from dogs in Florida.^{34,115}

Other syndromes reported in a few spontaneously diseased dogs include rheumatoid arthritis²¹¹ and myocarditis-induced cardiac arrhythmia.¹³⁸ These other signs are similar to those that have been reported in people. Unfortunately, the diagnoses in these naturally diseased dogs were often circumstantial—based on serologic data or microscopic evidence but no organism isolation. In people, conjunctivitis, vitritis, choroiditis, hepatitis, and myositis or fasciitis have been reported as rare syndromes and have not been reported in dogs. The strain used or the relatively short observation period in experimental studies may be the reason that the nonarthritic syndromes have not been reproduced in experimentally inoculated animals.

Fig 45-9 Erythematous lesion at attachment site of *A. americanum* associated with human infection by *B. lonestari* in Georgia. (Courtesy University of Georgia, Athens, Ga.)

45.4.1.2

Cats

Despite evidence for seropositivity for *B. burgdorferi* in cats, natural disease has not been described as a distinct clinical entity. Cats examined in endemic areas of the northeastern United States had infestations

Infectious Diseases of the Dog and Cat, 3rd Edition

with *Ixodes* ticks.¹⁵⁴ Approximately 13% of cats were seropositive according to indirect fluorescent antibody (FA) testing or an enzyme-linked immunosorbent assay (ELISA); however, no difference in positive results was found between cats with or without lameness. Similarly, cats that were screened as clinical patients in the United Kingdom had a low rate (4.2%) of seroreactivity.¹⁷¹ The seropositive cats in the United Kingdom study had no symptoms of lameness.

Cats may be more resistant than dogs to the development of clinical signs of Lyme borreliosis. As in dogs, inoculation of cultivated borreliae is associated with reduced virulence or immune recognition. Cats inoculated by various routes (i.e., parenteral, oral, conjunctival) with cultivated spirochetes developed IgG seropositivity; however, organisms were found only in the blood of the IV-infected and ocularly infected cats.³² The spirochetemia was transient, clearing by day 24, and only one cat had organisms in its tissues at necropsy. In contrast, when cats were inoculated with organisms directly from arthropods, they developed multiple-limb lameness and had joint, pulmonary, lymphoid, and central nervous system (CNS) inflammation at necropsy.^{75,76} Arthritis or meningitis seems to be the predominant manifestation that would warrant investigation of Lyme borreliosis in cats.

45.4.2 Relapsing-Fever Borreliosis

Borreliosis caused by a new borrelial spirochete was reported in two dogs from Florida.²⁵ Clinical signs included elevated rectal temperature, shifting leg lameness, hepatosplenomegaly, visible spirochetemia, and anterior uveitis, all similar to the signs of endemic tickborne relapsing fever. Many of the relapsing-fever spirochetes may infect dogs and cats as incidental hosts in the same way they are known to infect people (see [Table 45-1](#)). Additional studies are needed to determine the clinical significance of these infections.

45.5 DIAGNOSIS

Reports of Lyme borreliosis in people often exceed the geographic boundaries of known endemic foci.³⁶ Although travel accounts for a minor number of disparities, the overestimation of numbers of cases results from cross-reactivity to other infectious agents and from the inaccuracies of serologic procedures. Better studies to define the distribution of the disease in nature must be based on examination of ticks and wildlife, because isolation of the organism from ticks or reservoir hosts is more successful than from people and domestic animals.

45.5.1 Clinical Laboratory Findings

No specific hematologic or biochemical changes are pathognomonic of borreliosis, although CSF, joint fluid, and urine may show evidence of inflammatory changes. If a dog in an endemic area for borreliosis has leukopenia or thrombocytopenia, these hematologic abnormalities are likely caused by infection or coinfection with a rickettsial pathogen (e.g., *A. phagocytophilum*, see [Chapter 28](#)). The synovial fluid changes in dogs with borreliosis have been best substantiated by increased cell counts of 5000 to 100,000 cells/ μ l with neutrophils predominating (up to 95%). Protein concentration and turbidity are increased. CSF from human patients with neuroborreliosis demonstrates lymphocytic pleocytosis and a mild protein increase. Consistent CSF values have not been found in dogs with suspected neurologic dysfunction.

426

427

Infectious Diseases of the Dog and Cat, 3rd Edition

45.5.2 Serologic Testing

Lyme borreliosis is probably overdiagnosed in human and veterinary medicine because it has become a “trendy” illness.²⁴³ The presence of an elevated antibody titer to *B. burgdorferi* signifies exposure to the spirochete but does not prove that a current clinical illness is caused by the organism. In endemic areas, asymptomatic animals are often seropositive, possibly a result of adequate host immune responses or exposure to nonpathogenic forms of *B. burgdorferi* or other closely related spirochetes.⁷ In addition to seropositive results with a validated assay, the animal should have a history of tick exposure with compatible clinical signs and a rapid response to antimicrobial therapy. Unfortunately, the diagnosis of Lyme borreliosis has become more of a laboratory diagnosis than a clinical diagnosis. Clinicians depend on serologic testing because culture and microscopic detection of the organism from specimens of tissues or body fluids are uncommon. Rather than being thought of as a “test for Lyme borreliosis,” serologic studies should be viewed as determining “seroreactivity to *B. burgdorferi*.”²³⁰ Commercially available ELISA tests can be used to screen for potential exposure to *B. burgdorferi*; however, these should be followed by quantitative serial measurement of antibody titers or by immunoblotting to help determine the specificity of the infection.

45.5.2.1 Antibody Measurements Using Whole Spirochetes

Various problems have been noted with serologic testing. First, antigen preparations, techniques, and interpretations of different laboratories are not standardized. Matched sera sent to 10 commercial laboratories for antiborrelial serologic testing resulted in only 53% agreement among all sera tested.⁸⁷ Furthermore, nonspecificity of whole-cell borrelial assays is apparent in that other inflammatory conditions in people, such as autoimmune diseases, rheumatoid arthritis, syphilis, and periodontal disease, are known to produce cross-reactive antibodies, and similar reactivities probably occur in the dog and cat.

Serologic *screening procedures* clinically available for animals are the ELISA and indirect FA techniques. These assays use whole cells with many proteins that are present in other bacteria and therefore induce production of cross-reactive antibodies.^{33,68,144,170,229} The ELISA and indirect FA results have shown that *Leptospira*-positive sera can have low levels of reactivity to *B. burgdorferi*. Seroreactivity caused by infection with *B. burgdorferi* likely gives the highest titers, although cross-reactions should always be considered with any positive result. False-negative antibody tests results are rare.

Antibodies to the relapsing-fever-like organism described in dogs in Florida²⁵ cross-reacted with *B. burgdorferi*-derived antigens. They caused lower titers in the assay than the antigen from the new organism. Some of the reports of human and animal Lyme borreliosis in the western United States, where relapsing fever occurs, may be related to the nonspecificity of whole-cell ELISA or indirect FA. An immunoreactive protein, GlpQ, may be able to help distinguish these infections when used in immunoassays.²²³

The time course of serologic testing is also important in determining whether active or past infection is responsible for seropositivity. Early serodiagnostic results are usually negative because the immune response to *B. burgdorferi* develops gradually. Experimentally infected dogs developed IgG-ELISA-positive (whole bacterial cell) titers by 4 to 6 weeks after exposure.⁶ Titers were at their highest levels by 3 months after exposure and lasted for at least 2 years.²⁵⁰ Persistence of antibody responses have been found in people 10 to 20 years after they were diagnosed with active Lyme borreliosis.¹¹⁸ Antibody titers may decline after treatment and patients may become clinically healthy, but antibodies remain detectable for many years. Titer

Infectious Diseases of the Dog and Cat, 3rd Edition

increases almost always precede clinical lameness and fever in experimentally infected dogs.^{6,82} High or persistent IgG titers could indicate infection and as such are difficult to interpret on single specimens. Absolute values of titers can vary widely, therefore paired-sample titers should be submitted simultaneously to the same laboratory. Simultaneous measurements of IgG and IgM in a single specimen would theoretically provide more meaningful information than either titer alone. After experimental inoculation, IgM titers have been the first to increase and remain elevated for 2 months, after which they decline. However, in naturally infected dogs and people, IgM persists for many months so that a positive titer does not help to confirm recent exposure or infection.^{104,113}

In general, data from many laboratories obtained from indirect FA or ELISA methods suggest that titer results greater than 1:64 to 1:128 indicate the least significant level of reactivity. Titer results can be much higher in recently exposed, actively infected animals. High serum antibody levels seem to decline or disappear with antibiotic treatment, but increases that occur 6 months or later after termination of therapy are interpreted as proliferation of surviving spirochetes.^{246,248} Vaccinated dogs show seroreactivity for months to years after vaccination, making a diagnosis of *B. burgdorferi* infection difficult with whole-cell antigen preparations, although protective antibody titers after vaccination may decrease with time.

45.5.2.2

Immunoblotting

In most cases a two-step testing procedure should be used to confirm positive results from ELISA or indirect FA and substantiate the presence of Lyme borreliosis. Evaluating reactivity to selected antigens of *B. burgdorferi* organisms in a supplemental immunoblot (Western blot) helps identify sera that produce false-positive results in whole-spirochete assays because of cross-reactive antibodies; in addition, it is a powerful tool to differentiate infected from vaccinated animals (Fig. 45-10). The pattern of antibody reactivity after natural tick infection differs from that produced by vaccination. Sera from some dogs in endemic areas that are vaccinated with any product (lysate or recombinant antigens derived from *B. burgdorferi* organisms) exhibit reactivity to specific antigens that are expressed only on the surface of *B. burgdorferi* organisms in ticks or on borreliae raised in culture.^{71,83,106,158,228} The actual measured size of the bands (in kilodaltons) described in the following section varies in different investigations because of varied techniques and strain differences and should only be used as a guideline. After natural exposure to *B. burgdorferi*, antibodies develop to proteins in the range of 58, 41, 39, and 22 kDa, which represent p58, flagellin, periplasmic protein, and OspC, respectively.

Reactivity, particularly to OspA, OspB, and possibly OspF (31-, 34-, and 28-kDa bands, respectively), and 93-kDa bands occurs in vaccinated or parenterally inoculated dogs but is normally absent or occurs (rarely) very late in naturally infected dogs.^{6,90,92,139}

Newer ELISA tests using OspC proteins or using preparations derived from OspA- and OspB-deficient mutant *B. burgdorferi* strains, or using new recombinant *B. burgdorferi*-relevant antigens may help to improve the accuracy of serodiagnosis.

45.5.2.3

Antibody to Specific Outer Surface Proteins

ELISA testing for antibodies against specific recombinant proteins allows for discriminating between an active infection and past exposure and vaccination. The outer surface proteins of *B. burgdorferi* change from OspA and OspB to OspC after the tick ingests warm blood. Genetic expression of OspC proteins allows the organism to leave the midgut and enter the salivary glands and penetrate the host. The surface proteins revert

427

428

Infectious Diseases of the Dog and Cat, 3rd Edition

to OspA and OspB again when *B. burgdorferi* organisms reside within the arthropod host after it drops off, molts, and begins questing or when organisms are grown in culture for vaccine or diagnostic purposes. Whole-spirochete ELISAs using both OspA- and OspB-containing strains and deficient mutant strains are able to discriminate between natural and vaccine exposure,²⁷² especially when recombinant vaccine containing OspA was used. Using these ELISAs as an alternative to immunoblots, vaccinated animals can be differentiated from infected animals. Antibodies to OspA and OspB proteins rarely if ever appear later in the course of infection of the mammalian host because the organism alters its surface proteins in an attempt to avoid the host's immune system.

Fig 45-10 Immunoblot of sera from control-positive (C+) and control-negative (C–), vaccinated (V), and naturally infected (NI) dogs. (Courtesy R. Straubinger, University of Leipzig, Leipzig, Germany.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Although antibodies to OspA and OspB can indicate exposure to vaccines, detection of antibodies to OspC may be used to screen for active host infection. Proteins to OspC, which are only expressed by the organism during infection, are produced by recombinant technology. In ELISA testing of human sera for IgM, use of recombinant-produced OspC antigen had a higher degree of sensitivity in detecting recent infection than ELISA of whole cells or immunoblotting.^{73,192} Antibodies to recombinant OspC have also been most specific in determining infection in people with the varied borreliae that exist in Europe.¹⁰¹ Detection of borreliacidal antibodies against OspC was helpful in detecting experimentally infected dogs, and the magnitude of the titer paralleled the severity of infection and wider dissemination of the organism.³⁷ Borreliacidal antibodies to an OspC-containing strain did not increase after vaccination, which helped differentiate vaccinated from naturally infected dogs.

Variation in the genes that encode for the immunodominant VlsE surface lipoprotein of *B. burgdorferi* allows the spirochete to escape the host immune response when it enters the host. One immunodominant region of VlsE known as IR₆, originally isolated from a European species of *B. garinii*, is genetically, structurally, and antigenically conserved among *B. garinii*, *B. afzelii*, and different *B. burgdorferi* strains and genospecies. The genes for IR₆ are only expressed during infection of and replication in the mammalian host, and the protein is not found on organisms in unfed ticks or those grown at ambient temperatures for vaccine or diagnostic antigen. A recombinant-produced peptide known as C₆ reproduces the IR₆ sequence. Host antibody response to C₆ has been used in serodiagnostic testing of people and animals as a marker for host invasion and active infection. Testing for C₆ has been substituted for conventional whole-cell ELISA and subsequent immunoblotting in diagnosis of human borreliosis.^{11,161}

A commercial test—SNAP 3DX(TM) (IDEXX Laboratories, Westbrook, Me.)—is available that tests for antibody to the C₆ peptide. The C₆ commercial test can be used to more accurately differentiate between vaccinated and infected dogs compared to the whole-spirochete and immunoblot test methods (Table 45-3). In studies of dogs, C₆ protein has been used in ELISA testing of experimentally^{143,200} and naturally¹³⁴ infected animals. The anti-C₆ antibody response increased and waned more quickly after treatment than the antibody response measured by ELISA using whole-spirochete antigen extracts of *B. burgdorferi*.²⁰⁰ C₆ did not react with sera from healthy dogs, those with other infections (e.g., dirofilariasis, babesiosis, ehrlichiosis, Rocky Mountain spotted fever, leptospirosis), or those vaccinated with either OspA, whole-spirochete vaccines, or commonly used vaccines for other diseases.^{143,184} Use of this protein in serotesting may help determine the presence of active infection and if treatment has been successful may help eliminate the infection. Because not all dogs infected with virulent spirochetes become ill—and *B. burgdorferi* sensu lato and other closely-related strains and genospecies vary in pathogenicity—the C₆ antibody response may not always correlate with clinical illness in dogs. Clinical illness in seropositive animals may also relate to disease caused by other organisms that were present in the feeding tick.

The C₆ ELISA test has also been evaluated in cats on a limited basis.¹⁴¹ Of 24 cats tested in an endemic area, 17 had seropositive test results that matched those obtained by a whole-spirochete FA method. Five cats had negative antibody test results for both assays, and two negative test result samples had positive results at low dilutions with the FA method; one of these specimens had positive test results using immunoblotting. Cats were selected for their likeliness of exposure, and no correlation was made with clinical illness. As with dogs, if a cat is evaluated with clinical signs such as fever and joint swelling, the C₆ assay may be helpful as

Infectious Diseases of the Dog and Cat, 3rd Edition

an adjunctive test for diagnosis of Lyme borreliosis; however, coinfections with *A. phagocytophilum* (see [Chapter 28](#)) or other coincidental diseases must also be considered.

45.5.2.4

Cerebrospinal Fluid Antibody

Other approaches have been proposed to assist in the diagnosis of borreliosis. CSF antibody titers have been compared with those of serum in an attempt to diagnose neuroborreliosis in human patients.^{103,265}

Intrathecal production of specific antibodies to *B. burgdorferi* can be demonstrated if the ratio of CSF or serum *B. burgdorferi* antibody is greater than the CSF or serum albumin, total IgG, or specific IgG to another infectious agent (see [Chapter 3](#), Diagnosis of Distemper, and [Chapter 80](#), Toxoplasmosis). When the same

428

429

assay method is used for specific IgG, the specific method has the most reliability.^{99,240} Increased CSF IgM antibody directed against OspA, OspB, and OspC that did not have a corresponding increased in serum has been documented in people with neuroborreliosis.²¹⁶

Table 45-3 Comparative Serologic Test Results for Borreliosis in Dogs

SEROLOGIC TEST	NATURALLY INFECTED VIA TICK	RECOVERED FROM NATURAL INFECTION	VACCINATED WHOLE CELL	VACCINATED OSPA OR OSPB
IgM whole-cell ELISA or indirect FA ^a	Positive within first 60–90 days	Negative	Transient increase after vaccination	Transient increase after vaccination
IgG whole-cell ELISA or indirect FA ^b	After 60–90 days, positive for months or years	Positive for months to years	Positive for months to years	Positive for months to years
Immunoblot ^c	Numerous bands but not OspA or OspB ^e	Numerous bands but not OspA or B ^e	Numerous bands including Osp A or B ^e	Only Osp A or B protein bands ^e
C ₆ ELISA assay ^d	Positive	Negative	Negative	Negative

ELISA, Enzyme-linked immunosorbant assay; FA, Fluorescent antibody.

- a IgM whole-cell assays are the most nonspecific. Low to moderate titer increases occur with reaction to many spirochetes and some other bacteria. Only very high titers should be considered caused by spirochetes. Indirect FA may be more specific in this regard.
- b IgG whole-cell false-positive results caused by previous infections in recovered animals, vaccine, and reactions to many other closely related spirochetes. Indirect FA is more specific in this regard.
- c Immunoblot false-positive results include reactions with pathogenic and nonpathogenic isolates. Positive titer results persist even after infection has been eliminated.
- d C₆ false-positive results are caused by infection with *B. burgdorferi* sensu lato strains; some may be nonpathogenic. Subclinical infection occurs with *B. burgdorferi* strains when host immunity is adequately controlling infection.
- e P31 and P34 proteins.

An increased intrathecal antibody concentration was demonstrated in dogs with neurologic dysfunction.^{64,160} These results are difficult to assess because the dogs were from endemic areas, and no supporting histopathologic or culture findings were supplied.

Infectious Diseases of the Dog and Cat, 3rd Edition

45.5.3 Detection of Organism

45.5.3.1 Microscopic Detection

B. burgdorferi can be visualized in body fluids such as synovial fluid using dark-field microscopy or in tissues after nonspecific silver or specific immunologic staining methods. However, the spirochete density in clinical specimens is low.²⁶⁰ Microscopy is best used to detect organisms in the tissues of ticks. [Table 45-4](#) compares various features of organism detection methods.

45.5.3.2 In Vitro Cultivation

Culture of spirochetes from specimens of a diseased patient is the most definitive means of diagnosis but in most cases is difficult because of the low numbers of organisms present. The probability of isolating borreliae from blood is low because spirochetes migrate through connective tissues and only incidentally enter the circulatory system.²⁴⁹ Large quantities (20 ml) of ethylenediaminetetraacetic acid (EDTA) noncoagulated blood have improved isolation rates in people.²⁶⁷ A special medium called *Barbour-Stoenner-Kelley (BSK) medium* is required for borreliae isolation. Skin and collagen-rich connective tissues (fascia, pericardium, peritoneum, meninges, synovium) are the most consistent tissues for premortem or postmortem culture from dogs when specimens are taken at or near the site of tick attachment.^{37,249} The skin is clipped to remove the hair, a local anesthetic is instilled, and the area is carefully disinfected. Biopsy is performed using a 6-mm punch, and the specimen is placed in sterile tubes. Samples are processed with sterile pestles in medium, sequentially transferred to larger volumes of media, cultured at 33° C, and microscopically examined at 2-week intervals. Culture may be more sensitive than PCR before antimicrobial therapy²⁴⁶; however, culture is more time consuming than PCR (see [Table 45-4](#)).

45.5.3.3 Nucleic Acid Detection

Heralded as the supreme test for organism detection, PCR does have restrictions that have limited its use. Although most investigators claim its high specificity and sensitivity, PCR results can vary according to the designs of the selected primers (which are short stretches of artificially produced DNA used to induce specific DNA amplification). In contrast to culture, samples submitted for PCR require extensive handling. After enzymatic digestion of the sample matrix, DNA is recovered either by phenol/chloroform extraction (which is more efficient for DNA recovery but is considered more laborious) or by column purification. Subsequently, only a fraction of the pure eluted DNA (approximately 1% of the total amount, depending on the technique applied) is used for PCR analysis. With a low prevalence of organisms in the tissue sample, this statistically reduces the sensitivity of this assay tremendously, whereas the entire sample is submerged in medium during culture. Primers that target conserved DNA sequences can be used to detect various strains. Primers targeting plasmidial DNA are thought to be much more sensitive because of the multiple copies of plasmids present in the bacterium.^{198,245} PCR should be performed on synovial tissue biopsy rather than on joint fluid because it is more likely to contain the organism in infected patients. PCR cannot distinguish live from dead organisms. PCR has been used to detect *Borrelia* in the CSF of people with acute or chronic neuroborreliosis; however, the sensitivity is limited, and false-negative results¹⁸⁰ may occur. Instead, PCR performed on skin specimens was more sensitive than PCR on CSF or urine samples in these patients.¹³² PCR has been a valuable experimental tool and will likely become a more important clinical method for

Infectious Diseases of the Dog and Cat, 3rd Edition

diagnosis in dogs. PCR of skin is superior to culture in dogs that have been treated with antimicrobials or in untreated animals with long-term infections.²⁴⁶

429

430

Table 45-4 Comparison of Detection Methods of *Borrelia burgdorferi* in Clinical Specimens

DIAGNOSTIC METHOD	SPECIFICITY	SENSITIVITY	ACCURACY	QUANTIFICATION	USES
Microscopic detection, silver staining	Poor	Poor	Fair	Yes	Detection in tick and animal tissues
Microscopic detection, immunochemical staining	Good	Poor	Good	Yes	Detection in tissues
Antigen-capture ELISA	Poor	Fair	Poor	Yes	Screening method (substantiate with other tests)
Cultural isolation	Excellent	Good	Good	No	Definitive for laboratory use (takes 2–3 wk)
PCR probe	Good	Good	Good	Yes	Detection of infection in clinical specimens
Real-time PCR	Good	Excellent	Good	Yes	Detection and quantification for experimental studies

Infectious Diseases of the Dog and Cat, 3rd Edition

45.5.3.4 Detection of *Borreliae* by Other Techniques

Tissue specimens can be examined microscopically for pathogenic spirochetes by using specific antibodies labeled with fluorescent dyes or enzymes that produce a signal in a subsequent color reaction or with gold particles that are visible on transmission electron microscopy (EM). Xenodiagnosis, in which naïve ticks become infected after feeding on suspect infected hosts, has proved very reliable in the research laboratory setting but is expensive and time consuming.

45.6 PATHOLOGIC FINDINGS

Severely affected animals have grossly swollen joints with synovial effusion (Fig. 45-11). Inflammation within the synovial membrane is mild, and the effusion consists of fibrin and neutrophils in acute cases. In more chronic infections, dogs that have undergone seroconversion develop nonsuppurative inflammation within the synovial membrane and joint capsule. Peripheral lymphadenomegaly is present, especially in nodes draining the affected limbs.

In experimentally infected dogs, histologic lesions have developed in the lymph nodes, joints, pericardium, and skin.⁶ In addition, blood vessels (vasculitis, arteritis), peripheral nerves (perineuritis), and meninges (meningitis) have associated inflammation (Fig. 45-12).²⁵¹ Histologically, follicular enlargement and increased size of parafollicular areas in lymph nodes are evident. Skin biopsy samples have superficial perivascular lymphoplasmacytic infiltrates with mast cell accumulations. Renal lesions have not been found in experimentally infected dogs but were evident in naturally diseased dogs.⁴⁶ Glomerulitis, diffuse tubular necrosis with regeneration, and interstitial inflammation were found. These symptoms are more commonly found in certain breeds such as Labrador and golden retrievers. *Borreliae* can be demonstrated in tissues using silver impregnation methods or cytologic specimens with Giemsa stain. Silver stain of the kidneys of these dogs revealed rare spirochetes unrelated to lesion development.⁴⁶ In addition to hepatic degeneration, splenic hyperplasia, regional lymph node plasmacytosis, nonsuppurative meningoencephalitis, and pneumonitis, similar renal lesions have been noted in experimentally infected cats.^{75,76}

Infectious Diseases of the Dog and Cat, 3rd Edition

45.7 THERAPY

Because of the difficulty in obtaining an accurate diagnosis, antibiotics are often given empirically in an attempt to make a therapeutic diagnosis. Many reports exist of successful recovery after administration of antimicrobial drugs in dogs diagnosed with Lyme arthritis. Improvement often occurs within 24 to 48 hours after antimicrobial therapy is initiated. The greatest success is achieved with treatment in the initial phases of clinical illness. Clinical improvement after any therapeutic intervention should be viewed with caution because the acute limb and joint dysfunction is intermittent and often resolves after several days to weeks regardless of whether antimicrobials are given.¹⁵⁶ In addition, doxycycline can cause nonspecific antiinflammatory changes in injured joints and has been shown to be chondroprotective in noninfectious arthritis in dogs.²⁷¹

Early treatment is associated with a reduction in antibody titers and organisms in tissues and prevention or cure of clinical lameness and joint lesions.^{249,251} Most treatment is instituted for a minimum of 30 days, and amoxicillin, azithromycin, ceftriaxone, and doxycycline have all been used. However, on the basis of research studies, clearance of the organism after 30 days of treatment in dogs and rodents is questionable, and relapse and recrudescence of infection can occur after the antimicrobial therapy is discontinued.^{*} Similar treatment outcomes have been reported for human patients.⁵³ In addition to an inability to clear the organism, chronic inflammatory changes that occur in various tissues such as the joints may become self-perpetuating. Intraarticular persistence of *B. burgdorferi* nucleic acids occurs even though they cannot be cultured.^{23,251} The persistence may stimulate chronic immune and inflammatory processes. Those with more chronic borreliosis are less likely to improve or more likely to have relapses, even if treatment continues for weeks or months. Using clinical improvement after treatment as the basis for diagnosing borreliosis or other causes of bacterial or rickettsial polyarthritis is difficult because fever, joint distention, and lameness may appear and then disappear spontaneously. Furthermore, some antimicrobial drugs such as the tetracyclines have antiinflammatory effects.

Nevertheless, antimicrobial therapy is still the mainstay for treatment of borreliosis (Table 45-5). In vitro antimicrobial susceptibility testing has shown ceftriaxone, erythromycin, amoxicillin, cefuroxime, doxycycline, tetracycline, and penicillin G to range from most to least effective.¹¹⁶ Tetracycline, ampicillin, and erythromycin classically have been used to treat human and animal patients. Newer erythromycin derivatives, such as azithromycin, or third-generation cephalosporins, such as ceftriaxone, have been administered for more refractory human cases.⁴⁷ They are most effective for treatment of chronic infections. High-dose IV penicillin G has been advocated in an attempt to treat unresponsive animals. Borreliae are resistant to aminoglycosides and quinolones.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 45-5 Suggested Antibiotic Regimens for Lyme Borreliosis

DRUG ^a	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)	PREFERRED USES
Doxycycline	10 mg/kg	PO	12	30	Early disease, arthritis or neurologic manifestations, not for pups or kittens
Amoxicillin	20 mg/kg	PO	8	30	Early, arthritis or neurologic manifestations, young patients
Azithromycin	25 mg/kg	PO	24	10–20	Early disease
Penicillin G	22,000 U/kg	IV	8	14–30	Persistent arthritis, neurologic manifestations, or carditis
Ceftriaxone	25 mg/kg	IV, SC	24	14–30	Late neurologic or cardiac manifestations, persistent arthritis
Cefotaxime	20 mg/kg	IV	8	14–30	Neurologic manifestations
Chloramphenicol	15–25 mg/kg	PO, SC	8	14–30	Neurologic manifestations

PO, By mouth; IV, intravenous; SC, subcutaneous.

a See [Appendix 8](#) for additional information. Information on many drugs is based on extrapolation from literature on humans.

b Dose per administration at specified interval.

Doxycycline is generally the drug of choice because it is a lipid-soluble tetracycline and is relatively inexpensive. The theoretical advantages of lipid solubility are that a lower dosage is needed, tissue distribution is greater, and intracellular penetration is better than that achieved with conventional tetracycline. For growing animals, amoxicillin is recommended because doxycycline may stain the nails, skin, and enamel teeth. Doxycycline is less likely to cause this staining than other tetracyclines.⁵⁶ Ceftriaxone is reserved as parenteral therapy for meningitis in people. Treatment of people with ceftriaxone (2 g given IV once daily for 30 days) was effective in treating chronic Lyme encephalopathy.¹⁴⁸ Oral doxycycline (for 3 weeks to 2 months) may also be effective because it has been used to treat spirochetal meningitis in people.^{48,55}

Treatment of clinically healthy seropositive dogs with antimicrobial therapy is controversial. Many infected hosts have a natural immunity that prevents the organism from causing clinical disease. Furthermore, treatment of many dogs in endemic areas that might have antibody titers could lead to the development of additional resistant strains of spirochetes and other resident bacterial microflora. In contrast the incubation period can be prolonged; as immunopathologic consequences of infection develop, treatment may help to prevent the progression of these events during a subclinical period. Some veterinarians with this view advocate vaccination of animals in conjunction with treatment to prevent additional reinfection should the organism be eliminated.¹³⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

Nonsteroidal compounds offer relief for many of the painful arthritic complications, but judicious use is warranted because of their tendency to produce GI irritation. Glucocorticoids have also been hesitantly provided at very low antiinflammatory dosages in the management of persistent pain and swelling from chronic arthritis that cannot be completely controlled with one or more courses of antibiotics. An unfortunate consequence of persistence is that immunosuppression, such as that associated with administration of prednisolone in a dosage of 2 mg/kg daily for 2 weeks, reactivates latent disease.²⁵⁰ Dogs show no clinical signs of lameness while being treated but after therapy is discontinued, they develop signs of arthritis within 1 week.²⁵⁰ Immunosuppressive doses of glucocorticoids should definitely be avoided in chronically infected dogs because of infection exacerbation, or they should be given in combination with antibiotics.

Treatment and prognosis of renal dysfunction associated with Lyme borreliosis varies according to the stage and severity of the illness at the time diagnosis is made. With progression, marked proteinuria can lead to the nephrotic syndrome and systemic hypertension. In the early stages, ACE inhibitors and antiinflammatory drugs may be considered. As the disease progresses, animals may develop severe hypoproteinemia and decreased renal perfusion, which necessitates volume expanders, vasoactive agents, and osmotic diuresis. Unfortunately, like the polyarthritis, renal manifestations are usually progressive despite therapy.

* References 20, 159, 193, 246, 249-251.

45.8 PREVENTION

45.8.1 Antimicrobial Therapy

In people a single dose of doxycycline given at the time of identified tick attachment was 87% effective in preventing Lyme borreliosis.¹⁷⁶ Implementing this practice in dogs would be possible; however, the high exposure rate compared with the lower incidence of clinical illness in endemic geographic regions suggests a low degree of transmission and generally effective host immune responses. Early removal of ticks makes prophylactic treatment expensive and impractical.

45.8.2 Vaccination

Vaccines are marketed to prevent borreliosis in dogs.¹²² In Europe, the multiplicity of infecting species may make protection by vaccination more difficult. Recombinant protein OspA vaccines and whole-cell bacterins are commercially available for dogs (Table 45-6 and Appendix 3). Adjuvanted recombinant vaccine with expressed OspA and OspB proteins has protected dogs against tick-induced infection.⁴⁵ Unadjuvanted OspA, a lipoprotein, appears to offer equal protection.¹²² The vaccines are recommended for use beginning at 4 and 12 weeks of age, depending on the product. Primary vaccination schedules consist of two inoculations 3 weeks apart. Vaccines given early in life before exposure offer the best means of protection. Vaccination should not be universally recommended or provided as a replacement for adequate tick control measures. Dogs should be selected for vaccination based on the geographic area in which they reside or travel and by their geographic location, activities, and habits. That is, outdoor, hunting, or field-trial dogs that frequent known tick-infested areas should receive priority for vaccination. Dogs that are vaccinated with adjuvanted whole-cell vaccines or recombinant Osp vaccines before infection develop enhanced resistance to infection as demonstrated by an increased level of protective antibodies mainly directed against OspA (recombinant OspA vaccine) and minor antigens such as OspB and other currently unidentified antigens (bacterin vaccine).^{6,89,149,206,247,252} This type of protection does not appear to develop in the naturally infected animals. Reinfection is possible in animals

Infectious Diseases of the Dog and Cat, 3rd Edition

that are treated or recover from natural infections. Although OspA is an abundant protein on culture-derived *B. burgdorferi*, vertebrate hosts infected by tick bites rarely seroconvert to OspA.^{17,51} The OspA is expressed by borreliae in the midgut of unfed ticks, and the organism down-regulates this protein in response to a blood meal during transmission from the vector to the vertebrate host (see Pathogenesis in this chapter).²¹⁹ OspA allows the organism to adhere to and colonize the vector, and it is not present on spirochetes in engorged ticks.¹⁹⁴ Therefore to be effective, the vaccine-induced antibodies *must* be present in the host *before* the tick feeds. During tick feeding, OspC is expressed on the surface of the spirochete and appears on organisms that infect the feeding host.^{51,221,244}

Table 45-6 Comparison of Vaccines Licensed for Lyme Borreliosis in the United States^a

COMPANY	PRODUCT NAME	TYPE OF VACCINE	ADJUVANTED	ROUTE	MINIMUM AGE (WEEKS)	RECOMMENDED BOOSTER INTERVAL (YEARS)	CHALLENGE INTERVAL (DAYS)
Fort Dodge	LymeVax	Whole-cell bacterin	+	SC, IM	First dose: 6	1	150

					Second dose (interval): 3–4		

SC, Subcutaneous; IM, intramuscular.

a See [Appendix 3](#) for availability and combinations of antigens available.

b Contains two strains of *B. burgdorferi* sensu stricto.

In the presence of complement, the antibodies to OspA from the host cause an arrest of growth and prevention of salivary gland invasion in the ticks that feed on previously vaccinated animals.^{50,51} The borreliae are not eliminated in these ticks—their numbers are only diminished. In this manner, vaccine-induced immune protection begins in the tick before spirochetes enter the host. If experimentally infected animals are given passively administered OspA antibodies after tick engorgement, the animals stay infected. Vaccination of an

Infectious Diseases of the Dog and Cat, 3rd Edition

already infected animal does not clear the infection or prevent clinical illness.¹⁸ In a study of naturally infected dogs in a highly endemic area, the C₆ ELISA revealed that dogs vaccinated annually with a whole-spirochete bacterin had a much lower rate of infection (5%) than unvaccinated dogs (64%).¹³⁵

Because commercial OspA vaccines do not sustain protective titers, annual revaccination is recommended for high-risk dogs to maintain adequate titers. Furthermore, an anamnestic response against OspA does not occur because borreliae entering the host's skin no longer express this surface protein. In parenteral challenge studies, it was shown that protection is not afforded by prior immunization vaccines based on OspC.²⁰³ Although OspC is highly immunogenic, considerable variation in OspC among strains of *B. burgdorferi* and other species such as *B. afzelii* makes heterologous protection with this antigen difficult.¹⁰⁵ Existing *B. burgdorferi* infection in mice was cleared with passively administered sera from mice previously vaccinated with OspC. However, when actively vaccinated with OspC, mice had no beneficial protection against infection.²⁷³ Culture-confirmed reinfection of a person with different strains of *B. burgdorferi* sensu stricto has been reported, therefore cross-protection may be limited or does not exist among closely related strains and *Borrelia* species within the same genus.⁷⁸ In addition, cross-protection between *B. burgdorferi* sensu lato species inoculated into mice was not found.¹⁵

433

434

The disadvantage of vaccination is that the induced antibodies cause positive serologic test results for months or years and hamper the identification of infected animals. This problem may be resolved with use of the more specific immunodiagnostic tests, such as the previously described immunoblotting and C₆ assays. More important, whole-cell vaccines could theoretically lead to immunologic reactions that produce cross-reactive antibodies to host antigens. An additional theoretical but not yet documented disadvantage of the vaccine is the possibility that a hypersensitivity reaction may occur if it is given to a dog harboring large quantities of the organism.¹¹³ This has been more of a potential concern for whole-cell than recombinant Osp products, because the OspA targeted by the recombinant vaccines is missing on tissue-adapted *Borrelia* spirochetes. Therefore screening of older dogs for past infection is recommended, and those that have been previously exposed should not be vaccinated. Other concerns have been expressed about the exclusive use of recombinant OspA vaccines. Successful vaccination using these products requires high titers of OspA antibodies to be present at the time of natural infection because borrelicidal antibody titers are not maintained at high levels for extended periods. Regular revaccination may be very important. OspA is antigenically distinct among different *B. burgdorferi* species and other species such as those in Europe, so cross-reactive antibodies may not be protective. The additional antigens in a whole organism can assist in adjuvanting and broadening the immune response. Using one experimental whole-cell sonicated unadjuvanted vaccine produced more sustained borreliaicidal antibody titers and a superior response to challenge infection in dogs compared with an OspA vaccine.²⁴⁷

Local and systemic allergic reactions have been noted with whole-cell vaccines, but their prevalence rate is relatively low.¹³⁹ Borreliae are known to change their genotypic and phenotypic make-up to survive in the presence of organism-specific antibodies, so vaccine protection could lapse in the future or in particular geographic areas. Protection afforded by canine *Borrelia* vaccines is not absolute. Recommendations are to give two initial doses of the vaccine at a 2-week interval (see Table 45-6). Annual vaccination is recommended. In people, immunity was often much stronger after the third vaccine in the series.^{232,241}

Infectious Diseases of the Dog and Cat, 3rd Edition

45.8.3 Vector Control in the Dog and Cat

Supportive measures are needed to reduce the prevalence of infection in people and pets. Personal protection methods have received the most attention for tick control on pets. Individually applied products have included collars, topical powders, shampoos, dips or foams, sprays, spot applications, and oral products. Collars are impregnated with permethrin or amitraz. Amitraz-impregnated flea collars have prevented transmission of *Borrelia* infection to vector-exposed dogs.⁶⁰ Topical solutions contain selamectin, fipronil, and permethrin. Topical selamectin is effective in control of *Rhipicephalus* and *Dermacentor* species; however, it is was not as effective in treating dogs as permethrin.⁶¹ As a noninsecticidal method, daily combing to remove attached ticks may also be effective, as are the tick checks that are used on people. (For personal protection for people, see Public Health Considerations in this chapter. See [Chapter 94](#) for an additional discussion of vector control.)

45.8.4 Vector Control in the Environment

Application of acaricides to relatively large environmental areas is expensive and difficult. *Ixodes* species have a 2-year life cycle and become redistributed by various hosts after feeding, making it difficult to treat all stages with one application. Residual environmentally destructive compounds, such as the chlorinated hydrocarbons, have been the most successful method of controlling ticks, but their disadvantages are obvious.

A unique approach in tick control on wild mice has been adopted. The Maxforce Tick Management System (http://www.maxforcetms.com/maxforce_tms.html) is a small plastic box containing fipronil, as an acaricide, and a bait that is attractive to mice. Mice enter the box through a small hole. As a mouse moves through the box, it passes under a small applicator wick containing the fipronil.

Another method is to target infested rodents by placing cotton impregnated with permethrin insecticides near entrances to their burrows. To be effective, such acaricides have to target all reservoir hosts in a limited area. Treatment of all deer in a region with acaricides would inhibit the survival and reproduction of adult *I. scapularis*; however, the logistics of such an approach are overwhelming. Even if effective, vaccination of reservoir species would be impossible. Reduction of the deer population might help to decrease the number of ixodid ticks, but other mammalian hosts could still propagate the vectors.

45.9 PUBLIC HEALTH CONSIDERATIONS

The case definition of human Lyme borreliosis is (1) an erythematous rash or one objective sign of musculoskeletal, neurologic, or cardiovascular disease and (2) laboratory confirmation of infection.⁴ In 2000, 17,730 cases were reported from 44 states and the District of Columbia; the northeastern United States accounted for approximately 85% of the total cases. Since surveillance for human Lyme borreliosis was established in 1982, more than 140,000 cases have been reported from 50 states (www.cdc.gov). The sylvan cycle in nature has been found in only 19 states. Errors in reporting are probably due to underreporting, misclassification, and overdiagnosis. For example, tickborne relapsing fever caused by *B. hermsii* causes false seropositivity in Lyme borreliosis testing, resulting in unrecognized and underreported cases of relapsing fevers and overreported cases of Lyme borreliosis.⁵⁸ Serodiagnosis with older whole-spirochete antigen tests likely overestimated the prevalence of disease because of cross-reactivity.

The highest annual incidence of Lyme borreliosis is among children younger than 14 years and adults older than 30 years. Clinical signs usually begin from several days to 1 month after a tick bite. An expanding nonpruritic

Infectious Diseases of the Dog and Cat, 3rd Edition

ringlike erythematous lesion of at least 5 cm—an *erythema migrans*—may develop in the vicinity of the bite. Fever, myalgia, arthralgia, and headache (flulike symptoms) may accompany the lesion. Tick-bite–associated ECM lesions can be found on individuals in nonendemic regions and may be associated with organisms inoculated by bites of ticks that are not competent vectors of *B. burgdorferi*. These people have mild constitutional symptoms but test seronegative for *B. burgdorferi*. In contrast, people who become ill from *B. burgdorferi* infection develop recurrent joint swelling and musculoskeletal soreness. Meningeal signs include pain, sensory loss, behavioral changes, and recurrent headaches. Myocarditis is characterized by development of symptoms characteristic of atrioventricular conduction disturbances. Subclinical infections are also thought to occur; however, these are less frequent than previously realized because of cross-reactivity with older immunoassay methods.²⁴² Treatment of Lyme borreliosis in people is most rewarding during the early phases of illness. In chronically infected people with musculoskeletal or neurocognitive impairments, antimicrobial therapy is no more effective than placebo.¹²³

434

435

Personal protection measures for human tick control are not difficult to institute.^{*102} The most effective precautions include avoiding tick habitats, wearing long pants and long-sleeved shirts, taping socks over cuffs, tucking pants into socks, wearing light-colored clothing (to help identify ticks for early removal), and treating clothing and exposed skin with repellents. Agents containing diethyltoluamide (DEET) repel ticks and can be applied to clothing or exposed skin. Those containing permethrin kill ticks on contact but can only be applied to clothing. Additional measures include avoiding areas with tall grass and dense brush. Daily tick removal helps prevent transmission of infection. A delay exists between the beginning of tick feeding and the appearance of infectious spirochetes in tick saliva. Studies in animals show that little risk of infection exists within the first 24 hours of attachment and a maximum rate of infection between 48 to 72 hours of attachment or if the infected tick feeds until engorgement.⁵² The incidence of disease is also greater in people when ticks are attached for 72 hours or more.²³⁶ A single dose of doxycycline administered within 72 hours of a recognized *I. scapularis* bite efficiently prevented ECM in people living in endemic areas.¹⁷⁶

Although Lyme borreliosis is classified as a zoonosis, dogs, cats, and people are incidental hosts for a sylvan cycle that exists in nature. Lyme borreliosis is associated with outdoor activities that result in exposure to tick vectors. Dogs and cats do not appear to be a source for infection in people because they do not excrete infectious organisms in their body fluids (including urine) to any appreciable extent.⁶ Uninfected control dogs kept in direct contact with infected dogs for up to 1 year did not become infected or underwent seroconversion.⁶

Dogs and cats appear to be sentinel hosts but not reservoir hosts for human infection. In the same environment, dogs and cats have a greater risk of exposure than their human counterparts because of their greater likelihood of contacting the tick vector. Pets may bring infected ticks into the household, but ticks generally do not refeed after detachment. As with other tickborne illnesses, improper handling of ticks resulting in release of midgut contents onto abraded skin or mucous membranes might allow percutaneous penetration of infectious material. Even in areas where borreliosis is endemic, the risk of infection from a recognized ixodid tick bite is so low that prophylactic antimicrobial therapy of exposed people is not routinely recommended.²²⁷

The human vaccine that had been marketed in the United States was based on recombinant OspA because of the concern about whole-cell vaccine safety.¹³⁰ Although recombinant vaccines have been shown to be efficacious when used before exposure,^{232,241} their use has been limited because of concerns about potential but unproven side effects, and the product was withdrawn from the market in 2000.

* Additional information on Lyme borreliosis in people is available from (1) state and local health departments, (2) the Centers for Disease Control and Prevention (CDC) voice information system

46 CHAPTER 46 Miscellaneous Bacterial Infections

Carolyn R. O'Brien

Craig E. Greene

Russell T. Greene

46.1 MELIOIDOSIS

Melioidosis is an infection caused by *Burkholderia pseudomallei* (formerly *Pseudomonas pseudomallei*), an aerobic, gram-negative, motile bacillus with a single polar flagellum. The organism, which is restricted to latitudes within 20 degrees north or south of the equator, is a ubiquitous saprophyte, endemic to Southeast Asia, northern Australia, and the South Pacific where it is primarily isolated from moist soil and waterholes. Heavy monsoonal rains and winds may increase the risk of inhaling *B. pseudomallei*.⁸ Infection is thought to occur via cutaneous inoculation through wounds contaminated with soil or from bites of arthropod vectors, inhalation of dust, and ingestion of soil or contaminated carcasses. Infection can spread into the environment from an infected animal via caseous nodules that rupture.

The organism is a facultative intracellular organism, and the spectrum of clinical syndromes it causes in people and animals range from acute, fulminant septicemia and pneumonia, and chronic abscess formation and granuloma formation to mild or unapparent infections. Disease may appear many years after presumed exposure.²⁴

Cell-mediated immunity is important for successful elimination of infection in a host.¹³

Cases of canine and feline melioidosis appear infrequently in the literature, although anecdotal evidence suggests that infection in these species is more common in endemic areas than the literature would suggest.¹⁷ Seven military dogs stationed in Vietnam developed fever, myalgia, and abscess formation of multiple organs, including the dermis, lung, liver, kidneys, spleen, epididymis and testis,²¹ and an Australian dog developed disseminated cutaneous melioidosis after ingesting part of a goat carcass that had died of the disease.¹⁵ Of the four cases of feline melioidosis reported,^{7,17,22} three were presumed to have acquired the infection in Malaysia, with the remaining case having domicile in Northern Australia. Multifocal abscesses, lymphadenomegaly, hepatomegaly, and splenomegaly were most common in the affected cats (Figs. 46-1 and 46-2).

The diagnostic technique of choice is isolation of the organism from blood or lesions. Generally, *B. pseudomallei* is easily and inexpensively grown on routine media, although selective media such as Ashdown's agar may be needed to isolate the organism from sites where contaminating microorganisms are present. Thorough examination of Gram-stained smears of pus from lesions can sometimes identify small numbers of bipolar-staining gram-negative rods that may raise suspicion of the infection in endemic areas (Figs. 46-3 and 46-4). Immunologic assays for the detection of *Burkholderia* antigen and antibodies are available; however, none have been developed specifically for use in the dog or cat. In people, antibody detection may reflect exposure rather than active disease. Polymerase chain reaction can detect the organism in buffy coat and pus samples,^{2,9,20} and immunohistochemical methods can detect the organism in affected tissues.²³ Pathologic findings are abscesses in affected organs and draining lymph nodes (Figs. 46-5 and 46-6).

Treatment of melioidosis may be prolonged and is often unsuccessful, and relapses may occur. Surgical drainage of large abscesses may be required in conjunction with antimicrobial therapy. Antibacterial treatment is

Infectious Diseases of the Dog and Cat, 3rd Edition

recommended for small or disseminated lesions. The organism tends to be susceptible in vitro to trimethoprim-sulfonamide, fluoroquinolones, amoxicillin-clavulanate, some third-generation cephalosporins, tetracyclines, and carbapenems. Combinations of penicillins and aminoglycosides are ineffective. The most effective treatment of acute melioidosis in human patients appears to be high doses of parenteral ceftazidime given for at least 10 days, followed by a maintenance drug regimen of orally administered doxycycline, trimethoprim-sulfonamide, chloramphenicol, or any combination for 8 to 10 weeks.⁶ Adjunctive treatment with granulocyte colony-stimulating factor has helped reduce the mortality in people with septic shock due to melioidosis.^{6a} These drug regimens would likely also be effective in veterinary patients. However, amoxicillin-clavulanate has also shown to be adequate for maintenance treatment.¹⁹ It might be combined with an initial short concurrent course of parenteral imipenem.¹⁷ For appropriate therapeutic dosages, see [Appendix 8](#). Following a response to treatment, affected animals should be closely monitored for any signs of relapse.

Nosocomial transmission of infection has been suspected. The organism has survived in a parenteral anesthetic solution and an antiseptic cleaning agent containing cetrimide 3% and chlorhexidine 0.3%.¹⁶ Zoonotic transmission is thought to be extremely rare, although anecdotal reports of animal to human transfer have been documented.^{12,16} Generally, people in endemic areas become infected from the environment, as do animals.

46.2 GLANDERS

Pseudomonas mallei is a coccoid to filamentous, non-spore-forming, unencapsulated, nonmotile, gram-negative organisms that is a soil saprophyte of worldwide distribution. It affects primarily solipeds that ingest contaminated food or water, or the organism spreads between infected horses via aerosols. Cloven-hoofed animals are relatively resistant. Other animals, such as dogs and cats, and people have intermediate susceptibility. Glanders are infected by inadvertent contact with diseased horses, by consumption of contaminated horsemeat, or occasionally by wound contamination.

After intestinal or local wound infection, the organism produces bacteremia and spreads to the lymph nodes, nasal passages, and lungs where it produces nodular lesions resembling those of tuberculosis.

The organism grows on laboratory media, a process that can be facilitated by the addition of antimicrobials and growth factors. Serologic testing is used to confirm a diagnosis in solipeds, but accuracy in detecting canine and feline infection is uncertain.

436

Burkholderia mallei are sensitive to sulfonamides and tetracyclines. Dosages are listed in [Appendix 8](#).

46.3 *CHRYSEOMONAS* INFECTIONS

Chryseomonas luteola (formerly Ve-1) has been recognized as a cause of infection in people with bacteremia and of peritonitis from peritoneal dialysis.^{11,14,18} In people, *C. luteola* is usually associated with infections involving foreign materials, such as central venous catheters or joint prostheses. The 16S rRNA sequence of *C. luteola* supports the close relationship of this genus to *Pseudomonas*¹ and *Flavimonas*.

Disseminated melioidosis in two cats, *J Feline Med Surg* 5:83-89; with permission from European Association of Feline Medicine.)

In a dog with pyogranulomatous dermatitis and lymphadenitis, *C. luteola* and *Aeromonas caviae* were isolated as presumptive opportunistic bacteria from inguinal lymph node aspirates.^{16a} Infection with *C. luteola* was documented in a cat. Approximately 1 year after being diagnosed with diabetes mellitus, a 4.8-kg, 8- to 10-year-old domestic shorthaired cat was presented with a 4×8 cm swelling with purulent drainage from the right hip (Fig. 46-7). The animal was receiving subcutaneous insulin once daily. Pus from the mass was surgically drained, and amoxicillin, 20 mg/kg, was prescribed for 2 weeks. Four days later, the mass was still present; thus it was surgically removed and a drain was placed. The mass was submitted for histopathology. Six months later, a smaller mass developed at the lesion site. Cytologic examination of the exudate revealed large gram-negative rods. Biopsy findings were marked suppuration with primarily polymorphonuclear cell infiltration. Very large rod-shaped organisms were found within the inflammation.

437

438

Fig 46-5 Histopathology of liver microabscesses from a 5-year-old domestic shorthair cat with melioidosis. Fig 46-6 Histopathology of sternal lymph node from the same case. Note the neutrophilic exudate present in the cortical sinus. Involvement of the sternal lymph node was presumed secondary to the hepatitis observed in this case (H and E stain, bar = 200 μ m). (Courtesy Mark Krockenberger, University of Sydney, Sydney, Australia.)

Fig 46-7 Draining abscess on the hip of a cat containing *C. luteola*. (Courtesy Russell Greene, Phoenix Veterinary Internal Medicine Service, Phoenix, Ariz.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Specimens for bacterial culture yielded a convex, circular, yellow-pigmented colony within 24 hours on sheep blood agar. Lysis of the red blood cells was noted under the colony. Gram stain revealed it to be a very large, gram-negative rod. The isolate was identified as *C. luteola*. Kirby-Bauer testing revealed sensitivity to tetracycline, aminoglycosides, trimethoprim-sulfonamide, and enrofloxacin. The isolate was resistant to ampicillin, cephalothin, and oxacillin. The cat was treated with oral enrofloxacin, 22.7 mg (total dose), twice daily for 3 weeks and the lesion resolved.

47 CHAPTER 47 Plague

Dennis Macy

47.1 ETIOLOGY

Plague is caused by *Yersinia pestis*, a coccobacillus of the family Enterobacteriaceae, is a nonmotile, non-spore-forming, facultative anaerobic, gram-negative, bipolar-staining bacteria. The organism is nonsaprophytic and sensitive to desiccation and temperatures higher than 40° C, which make fomite transmission unlikely. This coccobacillus can survive for several weeks to months in organic material such as infected carcasses. Cold temperatures or freezing may prolong the viability of this organism for years. The organism grows slowly in culture even at its optimum temperature (28° C on blood agar or MacConkey agar), so cultures should be held for at least 48 hours before discarding. Colonies are much smaller than other Enterobacteriaceae and may be overlooked. *Y. pestis* produces a lipopolysaccharide endotoxin and a capsular envelope containing the antiphagocytic principal fraction I antigen. Three geographic variants of *Y. pestis* (*orientalis*, *antiqua*, and *mediaevalis*) can be distinguished biochemically but have identical virulence. Environmental and temperature fluctuations moderate the bacteria's expression of transmission and virulence factors. In this way the bacillus can survive in arthropods, transmit easily to mammalian hosts, and replicate readily in its new host, thus the infection has spread to most continents.

47.2 EPIDEMIOLOGY

Plague is a zoonotic infection transmitted among natural animal reservoirs. Infection is maintained by an obligatory flea-rodent-flea cycle involving chronically bacteremic rodent hosts and their resident fleas (Fig. 47-1). People and domestic animals are alternate hosts for *Y. pestis*. More than 230 species of rodents and 1500 species of fleas infected with the plague organism have been found. Despite this wide host range, only 30 to 40 rodent species serve as permanent natural reservoirs for plague; other rodent species are considered only temporary or amplifying hosts for the organism. Natural reservoir hosts are relatively resistant to plague infections, but susceptibility varies tremendously within a species and is based on geographic location, flea species, and environmental factors. Dog and cat fleas (*Ctenocephalides* species) are considered poor vectors for plague. In the United States, prairie dogs (*Cynomys* species), rock squirrels (*Spermophilus variegatus*), and ground squirrels such as *Spermophilus richardsoni* are commonly infected wild hosts. Mortality approaches 100% in these species.

Plague exists in various discontinuous regions on every continent except Australia (Fig. 47-2). These foci of plague are most frequently associated with semiarid, cooler climates that are usually adjacent to deserts. Each focus is unique in terms of its rodent reservoirs, flea vectors, and environmental factors. Common characteristics of endemic areas include the availability of rodent hosts with a short life expectancy and high reproductive potential and year-round flea activity. In the United States, plague foci are located throughout an area bounded on the east by the Rocky Mountains and on the west by the Pacific Ocean as well as in Hawaii (Fig. 47-3). In reservoir animals the disease may have explosive and often devastating sporadic or periodic epizootics among susceptible rodents. During epizootic outbreaks, the geographic area has spread into the high plains of Colorado, western Kansas, Oklahoma, and Texas. These temporary geographic expansions are caused by spread of the disease into highly susceptible ground squirrel populations but are usually not maintained for more than several years because of high mortality in these species. High mountain parks in Colorado and grasslands in California are also susceptible to rapid expansion of plague because of the presence of amplifying rodent species. People and pets exposed to infected rodents during these epizootics may develop plague pneumonia.

Infectious Diseases of the Dog and Cat, 3rd Edition

Rodent-burrowing systems maintain plague ecosystems by providing a moist environment for flea reproduction and housing very large numbers of animals such as prairie dogs. Burrows allow the exchange of infected fleas and allow interspecies spread when abandoned burrows are used by another species, such as rabbits, seeking refuge from a predator.

Cats and dogs acquire plague by ingestion of infected rodents or lagomorphs or possibly by bites from their prey's plague-infected fleas. Of 60 cats diagnosed with plague, 75% had hunted rodents.¹¹ Ten days after ingestion of rodents infected with *Y. pestis*, plague organisms can be isolated from the oropharynx and blood stream in approximately 50% and 20% of dogs, respectively. Dogs develop only mild clinical symptomatology, including fever and lymphadenomegaly, and undergo seroconversion. Wild and domestic cats are more susceptible to plague than dogs or other carnivores.

Domestic and wild cats have a susceptibility to *Y. pestis* that is similar to that of people and can be a source of infection for people. Disease in cats has been more common in the summer months; fewer cases are reported in the spring and winter. However, the time of year should not be used to exclude plague from the differential diagnosis. Raptors and other birds; wild carnivores, including black bears, coyotes, badgers, skunks, and raccoons; and domestic dogs are remarkably resistant to *Y. pestis* infection but may transport infected fleas or rodent carcasses. Rabbits, although not considered reservoir hosts, may become infected during enzootic outbreaks and serve as sources of infection in hunters.

47.3 PATHOGENESIS

The proventriculus of the flea is a valve-like organ with rough inner lining covered by cuticle that is interposed between the esophagus and the stomach (midgut). It mechanically lyses ingested erythrocytes, allowing smoother passage into the stomach while acting as a valve to prevent regurgitation of stomach contents.

439

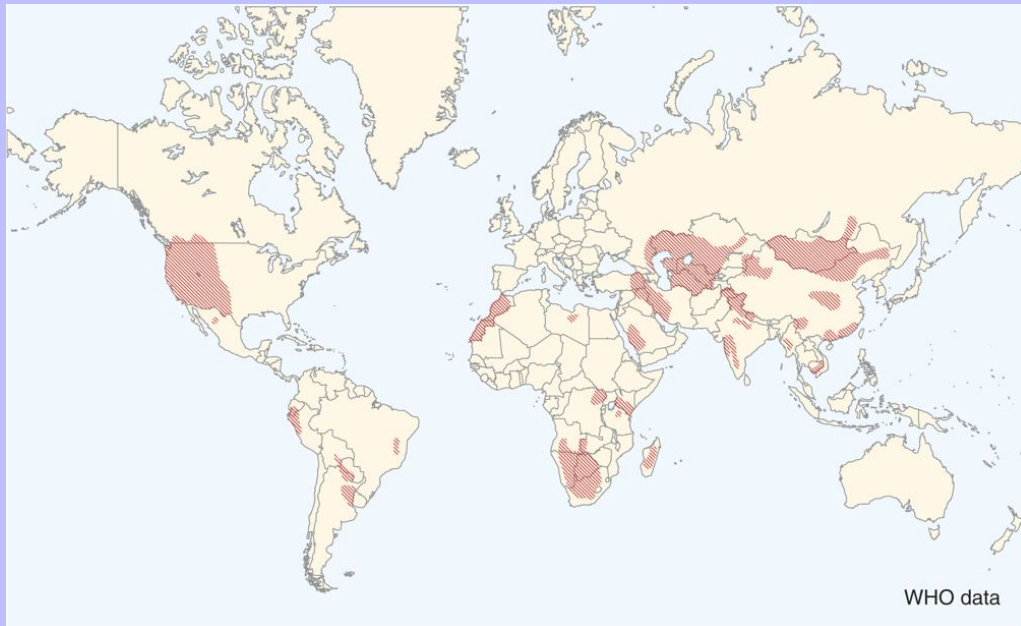

440

Fig 47-1 Epidemiologic features of plague. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

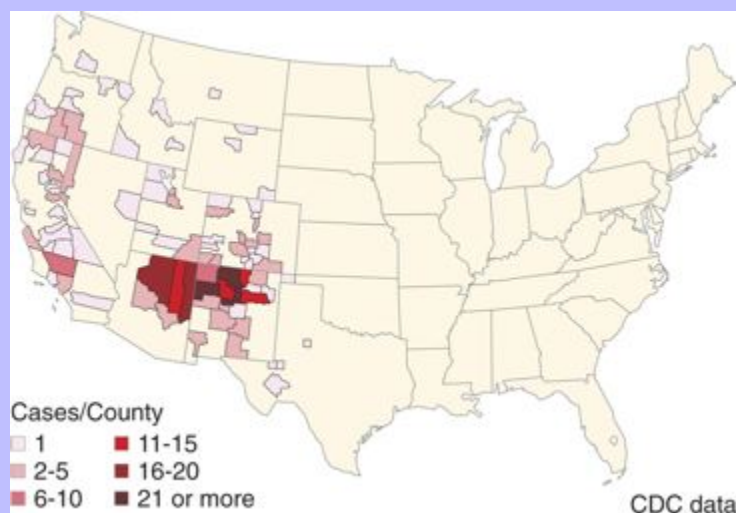

Fig 47-2 Known foci and areas of plague. (Data from the World Health Organization, Geneva, Switzerland. Map courtesy University of Georgia, Athens, Ga.)

Following ingestion of blood from an infected reservoir host, *Y. pestis* may be cleared by some fleas. In others, it replicates in high numbers in the flea stomach. A genetically encoded cytokine factor, *Yersinia murine toxin* (Ymt, a plasmid-encoded phospholipase D), is produced by virulent *Y. pestis* strains and allows the organisms to survive and replicate in the flea midgut by either antagonizing or down-regulating their antibacterial defenses.¹⁵ Ymt activity arises within *Y. pestis* after exposure to plasma ingested with the blood meal. After several days of successful replication, bacterial cells aggregate and attach themselves to the lining of the proventriculus. A second pathogenic factor, hemin storage phenotype (Hms), found in virulent strains of *Y. pestis* is required for the bacteria to colonize and block the proventriculus, resulting in a blocked flea. Hms genes facilitate the production of an extracellular matrix and biofilm that attach to the acellular surface of spines lining the interior of the proventriculus and cause the blockage.^{17a} Blocked fleas become starved for blood and attempt to feed more often. During these attempts, they regurgitate plague organisms into the bite wound of an uninfected host. Only blocked fleas transmit infection; they may die of starvation and dehydration. Fleas may remain infected for more than a year, allowing transmission of the disease long after the death of the host.

440

Fig 47-3 Distribution of human plague in United States from 1970 to 1997 by county. (Data from the Centers for Disease Control and Prevention, Atlanta, Ga. Map courtesy University of Georgia, Athens, Ga.)

Transmission of *Y. pestis* between most hosts occurs by flea bite. Although less common, transmission can also occur through contact of the organism with mucous membranes or broken skin or by inhalation of droplets from animals with pneumonic plague (see Fig. 47-1). Depending on whether the organism enters from a flea bite or through mucous membranes or broken skin, two distinct pathogeneses are possible. After a flea bite the organism is phagocytized by polymorphonuclear cells, in which *Y. pestis* cells are destroyed, and by mononuclear cells, in which *Y. pestis* not only survives but also multiplies. Infected mononuclear cells are carried to regional lymph nodes. As *Y. pestis* replicates, the lymph nodes become inflamed and swell, forming the bubo. Bubo most frequently develop in the submandibular and sublingual lymph nodes in the cat. Bubo eventually undergo necrosis and abscess formation, with eventual dissemination of the organism after 2 to 6 days via either the lymphatic channels or the blood stream to other organs, including the lungs. Replication in the mononuclear cells results in the production of a capsular envelope, which renders the organism resistant to further phagocytosis. When the organism is ingested or inhaled from contaminated tissues or fluids (rather than being transmitted through a flea bite), which is common in cats and other carnivores, the organism has already acquired this phagocytosis-resistant capsule from the previous host's mononuclear cells. Infection spreads more quickly, resulting in a shorter incubation period of 1 to 3 days.

Lesions at the site of inoculation are usually minimal. The most common visible lesions are in the lymph nodes that drain the site of inoculation. Marked lymphadenomegaly (bubo formation) develops, and nodes may abscess and drain a thick, creamy pus through fistulous tracts. Both deep and superficial lymph nodes in other parts of the body may become similarly infected after hematogenous or lymphogenous spread of the organism. In the bacteremic state, other tissues, such as the eye, liver, kidney, heart, spleen, brain, and lung, may become infected. Coalescing areas of infection and necrosis may result in parenchymal abscesses. *Y. pestis* contains endotoxins that may result in edema, septic shock, and disseminated intravascular coagulopathy. The clinical course may last 6 to 20 days.

Infectious Diseases of the Dog and Cat, 3rd Edition

Sixteen healthy cats that were experimentally infected with *Y. pestis* exhibited one of three responses. Thirty-eight percent died within 4 to 9 days after ingestion of a plague-infected mouse. The clinical course included fever (40.7° C to 41.2° C [105° F to 106° F]), depression, and submandibular lymphadenomegaly. Forty-four percent developed transient infections characterized by fever, depression, and lymphadenomegaly. In contrast to cats that maintained an elevated body temperature and eventually died of plague, the cats that survived demonstrated a sharp drop in body temperature by day 4 and had clinically recovered by day 14. Nineteen percent of the cats exposed to a plague-infected mouse showed no signs of clinical illness and had no hematologic changes.¹⁴ Most cats fed infected mice had *Y. pestis* cultured from their oropharynx and could have transmitted plague. In the natural environment the mortality in cats approaches 50%.²⁰ Cats with previous antibody titers to plague by either vaccination or natural infection generally have a more protracted illness but are not protected from bacteremia or death.

47.4 CLINICAL FINDINGS

47.4.1 Cats

In people and cats, three clinical forms of the disease have been recognized: bubonic, septicemic, and pneumonic plague. The most common and probably the least fatal form is bubonic plague. In cats, bubonic plague is associated with high temperature (40.6° C to 41.2° C [105° F to 106° F]), dehydration, lymphadenomegaly, and hyperesthesia. It is usually acquired by ingesting infected rodents, and the submandibular, retropharyngeal, and cervical lymph nodes in the area of inoculation become enlarged, form abscesses, and may drain. Drainage is not always apparent; however, cats with abscesses that spontaneously drain are more likely to survive. If allowed to progress, the bubonic form of plague may spread hematogenously or through the lymphatics to become the septic form.

Septicemic plague may develop with or without bubo formation. Hematogenous spread may result in involvement of virtually every organ in the body, although the most frequently involved organs are the spleen in people and lungs in cats. Features of septic shock, such as fever, anorexia, vomiting, diarrhea, tachycardia, weak pulse, hypotension, cold extremities, DIC, and marked leukocytosis are characteristic of the septic form of the disease in the cat. The septic form is usually fatal within 1 to 2 days after the presence of bacteremia.

Pneumonic plague in cats can develop *secondary* to hematogenous or lymphogenous spread of the organism and may be considered a sequel to bubonic or septic forms of the disease, whereas *primary* pneumonic plague is contracted through droplet transmission. Although cats normally do not contract primary pneumonic plague, they have been responsible for primary pneumonic plague in people who have contact with them. Pneumonic plague, whether primary or secondary, has the worst prognosis. In addition, persistent fevers of greater than 40° C (104° F) in cats are associated with poor prognoses. In people, untreated pneumonic plague is 100% fatal. In summary, plague should be considered when examining any febrile cat in endemic areas. Other atypical clinical signs have included ocular discharge, vomiting, diarrhea, dehydration, weight loss, a poor hair coat, a swollen tongue, tonsillar enlargement, necrotic stomatitis, facial ulceration, cellulitis, and abdominal distention.^{5,11}

47.4.2 Dogs

Clinical illness is less likely in dogs because of their apparent resistance to infection. Fever, anorexia, cervical and mandibular lymphadenomegaly and abscessation, and coughing have been observed in naturally infected dogs.²³

Infectious Diseases of the Dog and Cat, 3rd Edition

47.5 DIAGNOSIS

Although a clinician may be highly suspicious of plague in an animal on the basis of clinical and epidemiologic information, the diagnosis must be confirmed. Pneumonic plague may be indicated by pneumonic lesions visualized with thoracic radiographs (Fig. 47-4). *Y. pestis* is usually found in large numbers in infected tissues. In the clinical setting, it is important to collect samples and start antimicrobial therapy before the disease is confirmed. Needle aspirates from lymph nodes, blood, or infected tissue may be selected based on the clinical form of the disease in the patient. A quick Gram stain of these tissues usually reveals a monomorphic population of gram-negative organisms (Fig. 47-5), whereas common cat bite abscesses usually contain a mixture of organisms found in the feline oral cavity. Aseptically collected samples of fluids, tissues, lymph node aspirates, or blood should be submitted. Cultures of tonsils from experimentally infected cats have given consistently positive results, and the tonsils may serve as a source of infection of the saliva. Four or more slides for bacterial stains should be prepared by making impression smears or cytologic smears, allowing them to air dry, and then lightly heat fixing them over a flame. Care should be taken to avoid contact with purulent material while obtaining and preparing these samples. Individuals with the expertise to conduct plague tests are generally only found in public health laboratories in endemic areas and in the United States at the plague laboratory of the Centers for Disease Control and Prevention (CDC).

441

442

Fig 47-4 Thoracic radiograph of a cat with pneumonic plague. (Courtesy Dennis Macy, Colorado State University, Fort Collins, Colo.)

To make smears for direct fluorescent antibody testing, fluid specimens are applied to clean, thin, glass slides. One or two drops of sample fluid are placed on the slide into two circles made with a wax pencil. The drops are spread with a loop. With tissue specimens, impression smears are made within each circle. Slides are allowed to air dry and should be frozen if they cannot be shipped or examined immediately. This test provides the most rapid, presumptive diagnosis with good reliability.

Infectious Diseases of the Dog and Cat, 3rd Edition

For serologic confirmation, two serum samples should be collected 10 to 14 days apart for antibody titers against *Y. pestis*. Because dogs and cats in endemic areas frequently have high titers to *Y. pestis* that persist for a year or longer after exposure, a fourfold rise in titer is needed to distinguish active disease from previous exposure. Early in the course of disease, results of serologic testing are often negative.

Alternatively, specimens for culture may be collected using a sterile syringe by aspiration (before antimicrobial therapy is instituted) and placed in blood tubes or inoculated into transport media (Stuarts [Difco, Detroit, Mich.] or Cary-Blair [BBL, Cockeysville, Md.]). Refrigerated but not frozen, they are sent to a reference laboratory for confirmation. No fixatives or preservatives should be used. Veterinarians should not attempt to culture specimens, because class II precautions must be taken when isolating and identifying cultures from animals with possible plague. Samples should be wrapped in a double-thickness of plastic and padded to prevent breakage and leakage, which complies with federal requirements for transporting hazardous agents. It is recommended that the state veterinarian or health department be contacted before shipping samples to the Division of Vectorborne Infectious Disease.⁹⁷⁰ * Local public health officials may recommend that regional or state laboratories conduct the specialized serologic or cultural testing for plague (see [Appendix 5](#)).

Fig 47-5 Fine-needle aspirate of bubo from cat with plague. Note monomorphic population of bipolar staining coccobacillus organisms. (Courtesy Dennis Macy, Colorado State University, Fort Collins, Colo.)

At the laboratory, Gram stains are performed to determine staining characteristics, and Giemsa or Wayson stains are performed to determine whether the bipolar “safety-pin” appearance suggestive of *Y. pestis* is present. *Y. pestis* can be cultured on enriched blood agar but grows slowly, requiring 48 hours of incubation at an optimum temperature of 28° C to produce nonmucoid 1- to 2-mm gray colonies. If growth is observed, suspect isolates can be shipped to a reference laboratory. A polymerase chain reaction procedure has been developed to identify the presence of the organism in tissues, blood, and fleas.¹⁶

47.6 PATHOLOGIC FINDINGS

Cats, of which 50% die acutely, may have focal necrotic lesions of the adrenal glands, spleen, and liver, with evidence of secondary pneumonic spread of the disease. Those surviving for longer periods develop cervical or submandibular abscesses or bubos (Fig. 47-6). Consistent involvement of the cranial and cervical lymph nodes was apparent when cats were experimentally infected by the oral route.²⁹ In fatal cases, tonsils and submandibular, cranial thoracic, and mesenteric lymph nodes were also affected (Fig. 47-7). The normal nodal architecture is totally replaced by hemorrhage, suppuration, and necrosis (Fig. 47-8). Lymph nodes from cats that were euthanized after clinical recovery showed only lymphoid hyperplasia. Bacterial infiltration of the lung parenchyma, resulting in diffuse interstitial pneumonia, is characterized by focal areas of hemorrhage with clusters of bacteria. Coalescing areas of necrosis and abscess formation can occur. Because experimentally infected dogs develop only transient fever and lymphadenomegaly, no pathologic features have been described.

Infectious Diseases of the Dog and Cat, 3rd Edition

47.7 THERAPY

The decision to treat an animal for plague is seldom based on a definitive diagnosis. When plague is suspected on the basis of clinical or epidemiologic information, clinicians should not wait for laboratory confirmation before beginning specific antimicrobial therapy. All plague suspects should be handled by persons wearing gloves, gowns, eye protection, and high-density surgical masks. Animals with respiratory signs should have thoracic radiographs taken to determine whether they have pneumonic plague. Animals should be examined for fleas; if any are found, patients in surrounding cages and examination rooms should be treated with carbamates or pyrethrins. Bubos should be lanced and flushed with chlorhexidine diacetate (Nolvasan, Fort Dodge, Fort Dodge, Ia). Organic material, including tissues or pus-containing gauze pads, should be double bagged and incinerated. Routine disinfectants are effective in killing the plague organism and should be applied as a precautionary measure on cages and examination tables used in the care of infected animals.

Fig 47-7 Mesenteric lymph node from cat infected with plague. Node is markedly enlarged and hemorrhagic. (Courtesy P.W. Gasper, University of Maryland, College Park, Md.)

Y. pestis is susceptible to a wide variety of antimicrobial agents (Table 47-1). Unfortunately, multiple drug-resistant strains are being isolated with increasing frequency.⁹ Although *Y. pestis* appears to be sensitive in vitro to penicillin, it is resistant to β -lactam antibiotics in vivo. Aminoglycosides such as streptomycin and gentamicin are considered the most effective antibiotics against *Y. pestis*.^{2a} Treatment efficacy with penicillins or aminoglycosides has been increased in experimentally infected mice by using successive therapy with rifampin.²¹ Chloramphenicol is used in the treatment of patients with central nervous system spread of plague organism. Administration of tetracyclines has been associated with relapse, presumably caused by the development of bacterial resistance or poor absorption from the gastrointestinal tract. Tetracyclines (with doxycycline being preferred) are given primarily for the bubonic form of the disease and for prophylaxis. The fluoroquinolones and doxycycline have been shown to be effective in the treatment of plague in mice.^{4,27} No clinical data exist on the effectiveness of fluoroquinolones, so their use in treating cats or dogs is not recommended. Infected cats should be

Infectious Diseases of the Dog and Cat, 3rd Edition

treated for a minimum of 21 days. Treatment should continue far beyond the resolution of bubos and pneumonic changes. Patients should be isolated during the first 48 to 72 hours of antibiotic therapy. Animals with plague pneumonia should remain hospitalized for slightly longer periods to avoid inadvertent exposure to caregivers in their home environment.

Prophylactic therapy with a tetracycline is indicated in asymptomatic animals exposed to plague and should be continued for 7 days. People exposed to plague while caring for plague-infected animals are usually treated with a similar therapy by a physician. The prognosis depends on the clinical form of the disease and the species infected.

b Dose per administration at specified interval (see [Appendix 8](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

c Renal function must be closely monitored because of potential nephrotoxicity.

47.8 PREVENTION

People and domestic animals have intruded into the natural ecosystem in which plague circulates. Elimination of plague in wild rodent populations is generally impossible. Risk factors for cats include living in or visiting rural areas in endemic regions, flea infestation, and hunting or eating rodents and rabbits. Veterinarians should be especially alert when evaluating sick cats during plague outbreaks and take appropriate precautions to protect themselves, their employees, and their clients. Examination of fleas taken from patients may quickly reveal whether they are of rodent source. Flea control in dogs and cats should be stressed in enzootic areas, because pets have ample opportunity to spread fleas to their owners. Fipronil has been effective in control of vector fleas from ground squirrels.²² Dogs and cats should not be allowed to come in contact with burrows or have access to carcasses of dead rodents or lagomorphs. Residents in endemic areas should be encouraged to decrease the availability of food and habitats (such as trash or garbage piles) for peridomestic host species, which may become infected during enzootic outbreaks. Climate dynamics such as increased rainfall that augment flea and small mammal populations enhance the risk of plague. Local and state health officials may institute rodent control measures but not before flea control has been instituted in the area.

In the veterinary hospital, inadvertent nosocomial spread to the veterinary hospital staff is a serious problem that can occur before a diagnosis has been confirmed. Therefore veterinarians in endemic regions should be extremely aware of possible plague. Risk of droplet or airborne spread to caregivers can be decreased with protective well-fitted surgical masks and eyewear. Droplets, which can travel up to 2 m, can be generated by coughing, by sneezing, or during lavage or aspiration of abscesses. Infected or possibly infected animals should be isolated from other animals and have their movement restricted. Contaminated droplets do not remain suspended, so special measures for ventilation and air handling are not required. After pneumonia has been discounted or the animal has been treated for at least 72 hours, standard precautions for handling contagious diseases can be implemented. Standard precautions include washing hands before and after contact with animals, wearing gloves when contacting body fluids or tissues, and wearing gowns to minimize transfer of the organism to clothing, other animals, and the surrounding environment.*

444

445

Killed and modified live vaccines for *Y. pestis* have been produced for human use. The killed formalin-fixed virulent whole-organism preparation was used in the United States until 1999. No plague vaccine is approved for use in the United States. Even in areas where vaccine is available, vaccination of veterinary staff is not recommended.¹² Immunization of cats with the killed vaccine did not protect them against bacteremia or death and prolonged the clinical course of the disease. In the past, vaccination has been recommended for all laboratory and field personnel who are working with *Y. pestis* and for persons engaged in field operations in areas of enzootic plague. Experimental subunit vaccines have been evaluated and appear to protect against bubonic and pneumonic plague.²⁸

* See www.cdc.gov/ncidod/hip/ISOLAT/Isolat.htm for additional information on biocontainment of plague-infected animals.

47.9 PUBLIC HEALTH CONSIDERATIONS

Human plague is seasonal, with most cases in the Northern Hemisphere occurring between March and October. A total of 377 cases in people were reported from 1970 to 2001.²³ The incidence of human plague in the United States is increasing. The 105 cases that occurred in 8 western states during the 1970s represented the largest

Infectious Diseases of the Dog and Cat, 3rd Edition

number in the continental United States in any decade since 1900 to 1909. In decreasing order of number of cases, 90% of the human cases of plague reported were from New Mexico, Arizona, Colorado, and California. Since 1949, New Mexico has reported annually more than 50% of plague cases. In one survey, 82% of human plague cases were transmitted by flea bites, 15% by direct contact with infected wild animals, and 3% by contact with infected domestic cats. A review of 297 cases of plague in the western United States found that 7.7% of the cases in people were associated with handling infected cats.⁷

From 1977 to 1998 the CDC confirmed 23 human plague infections acquired through inhalation of *Y. pestis*-infected droplets expelled from cats with secondary plague pneumonia.¹² Approximately one fifth of those infected died, and one fourth of those infected were veterinarians or their technicians. The remaining three fourths of those infected were owners of or people caring for sick cats. Approximately three fourths of the people developed bubonic plague, one person developed septicemic plague, and the remainder developed a pneumonic infection.²³ The overall death rate in the United States for humans treated for plague is 15% to 22%. The two primary reasons people die from this treatable disease are that (1) they delay seeking medical attention, and (2) a clinician does not recognize the disease as plague. These factors are even more likely to play a role when people acquire the infection in enzootic areas and travel to areas of the United States where clinicians have never seen patients with plague. The death rates in such instances has been 80%. Enhanced awareness is needed for early diagnosis and successful treatment.⁷

All free-roaming cats in an endemic area must be considered at risk for exposure to plague. Veterinarians and their assistants are more likely to be exposed to plague because of their occupations. People may become infected by inhaling respiratory droplets from animals infected with secondary pneumonic plague, through broken skin or mucous membranes while handling infected tissues and body fluids, or through bites of plague-infected fleas. Patients suspected of having plague should be hospitalized and isolated immediately, and attempts should be made to limit the number of individuals caring for infected animals. They should be educated about plague transmission and advised to wear protective clothing and gloves while treating and caring for infected pets. Routine disinfectants should be applied to cages and examination tables, and flea control should be instituted in the area housing affected infected animals. Veterinarians who diagnose plague in cats should advise the cat owners to contact their physicians immediately. Local and state health authorities should be notified early in the management of plague-infected animals.

47.10 PLAGUE AS A BIOLOGIC WEAPON

Plague has caused more human deaths than most other diseases and wars combined. It is estimated to have killed one fourth to one third of Europe's population in the Middle Ages. Antibiotic therapy and public health advances make a natural global pandemic unlikely. However, because *Y. pestis* is extremely virulent, can be transmitted from human to human, and has antibiotic-resistant strains that have emerged naturally or been developed in the laboratory, plague is considered a high-priority bioterrorism agent. The plague bacillus has been classified as a Category A, Critical Biologic Agent, by the CDC.¹ Plague was first used as a weapon in the 14th century when the Tatar army catapulted diseased corpses over enemy walls in the Crimea. In World War II the Japanese army secret unit 731 reportedly sprayed grain laced with plague-infected fleas over Chinese cities, causing plague outbreaks. In the 1950s and 1960s the American and the Soviet biological weapons programs developed techniques to aerosolize plague particles. The intentional release of a plague cloud could result in an outbreak of fatal pneumonic plague. In 1970 the World Health Organization reported that, in a worst-case scenario, 50 kg of aerosolized *Y. pestis* released over a city of 5 million people would cause 150,000 people to develop pneumonic plague, 36,000 of whom would die. Plague bacilli would remain viable as an aerosol for 1 hour for a distance of up to 10 km. Inhabitants attempting to leave the area would spread the disease even more. The most likely first

Infectious Diseases of the Dog and Cat, 3rd Edition

indication of an attack would be a sudden outbreak of severe pneumonia and sepsis. The presence of hemoptysis in previously healthy people and symptoms of fever, cough, shortness of breath, chest pain, and rapid death suggest plague. The secondary spread of plague from person to person, animal to person, and person to animal would be likely.

Infectious Diseases of the Dog and Cat, 3rd Edition

48 CHAPTER 48 Tularemia

Craig E. Greene

Brad M. DeBey

48.1 ETIOLOGY

Tularemia is an acute bacterial infection of many avian and mammalian species, including dogs and cats and occasionally people. Terrestrial and aquatic mammals serve as reservoirs for the disease. It occurs throughout the temperate region of the Northern Hemisphere, predominantly between 20 and 70 degrees latitude.¹⁷ The etiologic agent, *Francisella tularensis*, is a small (0.2×0.2 to $0.7 \mu\text{m}$), pleomorphic, gram-negative, non-spore-forming bacillus. The tularemia bacillus has two main biovars: type A (subsp. *tularensis*; previously *nearctica*) and type B (subsp. *holarctica*; previously *paleartica*). Type A strains ferment glycerol and are highly virulent for laboratory rabbits (*Oryctolagus cuniculus*), and type B strains do not ferment glycerol and are avirulent for rabbits. Type A strains are associated with a tick-rabbit cycle of infection and occur only in North America. Type B strains have a more complex epidemiology—involving rodents, ticks, mosquitoes, mud, muskrats, beavers, and water—and occur throughout the Northern Hemisphere. Both type A and B strains have been isolated from cats in the United States.³ Human illness is generally more severe with type A strain infections.²⁸ Two less frequently isolated biotypes include subspecies *mediasiatica*, found in Kazakhstan and Uzbekistan, and *novicida*, primarily from North America. Subspecies *novicida* is of low virulence.

48.2 EPIDEMIOLOGY

Tularemia is endemic in the Northern Hemisphere between the latitudes of 30 degrees N and 71 degrees N (Fig. 48-1). This area includes much of Eurasia to countries on the Mediterranean coast of Africa. In North America, this region ranges from the Arctic Circle as far south as Guadalajara, Mexico. Tularemia is a rural disease in people and in their pets as a result of contact with wildlife reservoirs, their vectors, or the contaminated environment.

In Eurasia, cricetine rodents (e.g., meadow voles, lemmings, muskrats), hares, and bites of infected mosquitoes are important sources of infection. In North America, the principal animal sources are the cottontail rabbit (*Sylvilagus* spp.) and wild hares and rodents, as well as the ticks that infest them. Biting flies mechanically transfer the infection.

In the United States, four tick species constitute the primary vectors for dogs and cats: the wood tick (*Dermacentor andersoni*) found in the Rocky Mountain region; the American dog tick (*D. variabilis*) found in the eastern two-thirds of the country, as well as in the Pacific coastal states; the Pacific Coast tick (*D. occidentalis*) found in California and Oregon; and the Lone Star tick (*Amblyomma americanum*) found in the southern central and southeastern states. The incidence of infection for people in the United States is presented in Fig. 48-2.

Because the epidemiology of tularemia is complex, and its host species so diverse,¹⁷ only the aspects that are important in its transmission to dogs and cats are discussed here (Fig. 48-3). Various tick species, which are true biologic vectors for the disease, serve as both reservoirs and vectors of tularemia. Infection can pass transovarially in ticks, and infection persists for life. Amplification of the infection rate in a tick population occurs when uninfected ticks feed on bacteremic animals. Although ticks are capable of transmitting tularemia at all three

Infectious Diseases of the Dog and Cat, 3rd Edition

stages of their development, the adult and, less commonly, nymphal stages are most important in transmission to dogs, cats, and people.

Cats and dogs may also be infected when they hunt or eat infected rabbits or rodents. Transmission can also occur through bites or scratches from other predators with contaminated teeth or claws. Infection in people has developed following inhalation of aerosols or dusts or ingestion of food or water contaminated with the organism. Numerous blood-feeding insects (such as mosquitoes or biting flies) can serve as mechanical vectors for the disease when their mouthparts become contaminated when they bite infected hosts.

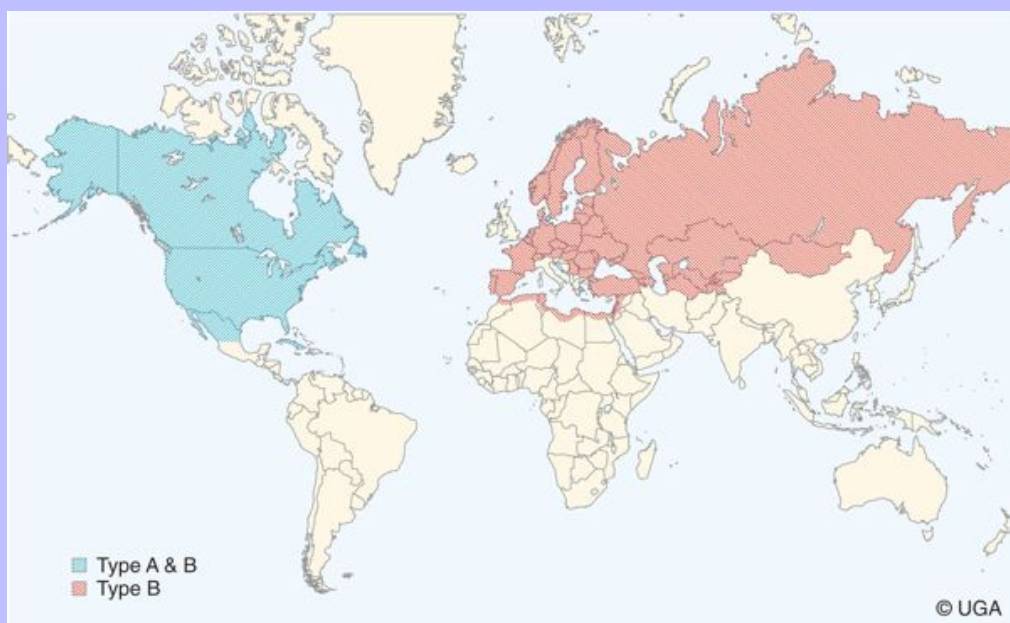

48.3 PATHOGENESIS

In the laboratory, *F. tularensis* requires enriched growth media and replicates in a variety of cells. In vivo, it is a facultative intracellular pathogen. Macrophages are the major host cell, and the organism's capsule is thought to be important in its intracellular survival. The infectious dose is extremely low, and inhaling 10 to 50 colony-forming units is enough to induce disease.

The clinical presentation of human tularemia varies by route of infection and initial sites of localization. Typically, a localized infection occurs at the primary inoculation site and is associated with prominent regional lymphadenomegaly. In a highly susceptible host, only less than 50 organisms can cause infection by parenteral inoculation, while at least 10^8 are needed for oral infection. Subsequent bacteremia and multiorgan involvement are common. The lungs, spleen, liver, lymph nodes, and skin are the sites of embolic spread (Fig. 48-4). Early embolic lesions, which begin as microabscesses, progress to granulomatous inflammation as the body attempts to wall off the infection. Bacteremic disease without antecedent localized infection is referred to as typhoidal tularemia. Cell-mediated immunity plays an important role in recovery.

447

Fig 48-1 Worldwide distribution map of tularemia. (Map courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 48-2 Yearly incidence data of tularemia in the United States for 2002. (Data from the Centers for Disease Control and Prevention, Atlanta, Ga. Map courtesy University of Georgia, Athens, Ga.)

A similar disease pattern appears to occur in dogs and cats. The severity of illness in experimentally infected dogs varies with age; puppies are more susceptible than are young adults. Ingestion of infected tissues or intradermal (ID) challenge produced milder disease than intranasal (IN) challenge.^{13,19} When dogs were fed infected tissues, an acute 5-day illness began after a 48-hour incubation period.¹⁹ Fever (40.2° C [104.4° F]) and a mucopurulent discharge from the nose and eyes were present. Transient ulceroglandular tularemia follows ID challenge with concomitant development of fever, pustules at the inoculation site, and regional lymphadenomegaly.

More serious illness characterized by septicemia and high mortality follows subcutaneous (SC) or intramuscular (IM) inoculation. Draining abscesses develop at the inoculation sites and are associated with regional lymphadenomegaly and high temperature and with systemic dissemination of the disease after 1 week. At this time, the dogs appear obviously ill, have mucopurulent ocular and nasal discharges, and develop a vesiculopapular skin rash.

Cats have become ill after eating experimentally infected guinea pigs.³⁰ Although some cats appear unaffected, younger cats succumb primarily to systemic (typhoidal) infection characterized by generalized lymphadenomegaly and miliary abscess formation involving the liver and spleen.

After SC inoculation, similar findings have been apparent, and young kittens appear most susceptible.³⁰ Some SC- and IN-inoculated cats have had areas of bronchopneumonia from which *F. tularensis* was isolated, as well as splenomegaly and multifocal hepatic necrosis.

Respiratory disease resulting from inhaling *F. tularensis* has a more virulent course. This form has been observed more in people than animals. Coughing, fever, hilar lymphadenomegaly, and pulmonary infiltration occur. Mortality is more common with this form of illness.

Infectious Diseases of the Dog and Cat, 3rd Edition

48.4 CLINICAL FINDINGS

48.4.1 Dogs

Despite the ability to produce experimental infections and high seroprevalence, indicating exposure in endemic areas, naturally acquired infections in dogs have been rare.* Dogs are considered relatively resistant to tularemia. Typically, a dog develops a brief episode of anorexia, listlessness, and low-grade fever. Sudden death of uncertain cause has occurred in a dog a few days after sniffing a dead infected rabbit. Another dog developed multifocal draining abscesses in the SC tissue and superficial lymph nodes in addition to fever, anorexia, myalgia, and shivering. Uveitis and conjunctivitis developed in the left eye, with subsequent transient conjunctivitis and corneal clouding in the right eye.

* References: 5, 8, 13, 17, 24, 24a.

48.4.2 Cats

Based on the large number of reports, cats are more susceptible to tularemia compared with dogs. The spectrum of illness associated with spontaneous feline tularemia has not been well described. In a series of three typhoidal cases, pertinent clinical signs included fever; marked depression; pharyngeal, cervical, mesenteric, regional, or generalized (or any combination) lymphadenomegaly; palpable splenomegaly and hepatomegaly; acute shallow oral or lingual ulcers (or both); icterus; and panleukopenia with severe toxic changes of neutrophils.³ The oral and lingual ulcers were compatible with infection resulting from ingestion of infected rodents or rabbits.

Other cases in cats have been briefly described in epidemiologic reports of human cases.* Implicated cats had frequently eaten or mouthed wild rabbits before the onset of clinical signs. Variable signs of fever, anorexia, listlessness, lymphadenomegaly, draining abscesses, and, occasionally, icterus and death were reported. Some cats had no signs of illness.

* References: 6, 15, 17, 22, 26, 30.

48.5 DIAGNOSIS

Laboratory abnormalities in tularemia have been leukocytosis with a left shift, thrombocytopenia, increased serum hepatic transaminases, and hyperbilirubinemia.

Infectious Diseases of the Dog and Cat, 3rd Edition

Testing for serologic evidence of microscopic agglutinating (MA) antibody is the most commonly used diagnostic procedure. Both dogs and cats develop antibodies, but titers tend to be lower than those observed in people. Titers from 1:140 to 1:160 are typical of recent infections in dogs.^{19,28} Using an MA method in cats, serum antibody titers to *F. tularensis* have been above 1:20.³⁷

Enzyme-linked immunosorbent assay techniques have been developed to detect antibodies to specific *F. tularensis* antigens in infected people,⁴ but their usefulness for testing canine and feline sera is uncertain. Indirect fluorescent antibody methods have also been used for serotesting. A fourfold increase in antibody titer is required to confirm active disease; however, a single titer of at least 1:160 suggests active disease.³⁸ Direct FA methods can be used to detect the coccobacillary organisms in exudates and tissues, even with paraffin-embedded tissues. Polymerase chain reaction (PCR) has also been used to confirm infection. Lymph node aspirates have been of a mixed lymphoid cell population characteristic for hyperplasia.

The isolation of *F. tularensis* from exudates or tissue specimens is the definitive method of diagnosis. The organism is fastidious and must be isolated on special media, such as supplemented chocolate agar, or by initial inoculation of a susceptible laboratory animal with subsequent culture of the liver and spleen. Blood-glucose-cysteine agar or brain-heart infusion agar supplemented with blood is needed for isolation at 37° C. Characteristic dewdrop colonies are isolated. Biosafety level 3 measures must be used to handle infected tissue. Refer to [Appendix 5](#) for a listing of laboratories that perform this isolation.

The infectious dose for humans is less than 100 organisms, inhaled as an aerosol, accidentally inoculated, or splashed in the conjunctival sac. Cultures of *F. tularensis* and necropsies of animals with suspected tularemia should be performed therefore only in laboratories with adequate biosafety equipment. Testing of aspirated pus with PCR has been used for definitive diagnosis of this infection in people.¹⁰

48.6 PATHOLOGIC FINDINGS

Gross necropsy findings in affected dogs and cats are similar. Most of this information has been obtained in experimentally infected animals. Lymph nodes are often markedly enlarged in a regional or more generalized pattern and they often contain multiple foci of necrosis. Draining sinus tracts may arise from the nodes. Hepatomegaly or splenomegaly, or both, may be present. Multiple small, grayish foci representing necrosis are commonly found in the spleen, liver, lung, and, occasionally, heart ([Figs. 48-4 and 48-5](#)). Segmental to diffuse hemorrhage of the small and large intestines has been reported in cats.³ These same cats had prominent ulceration in Peyer's patches and colonic lymphoid follicles. Fibrinosuppurative to granulomatous inflammation is observed in many parenchymal organs ([Figs. 48-6, A and B, 48-7, and 48-8](#)). The causative bacteria are not easily demonstrated in the lesions except by specific FA or other immunohistochemical stains ([Fig. 48-9](#)).⁹ Where small numbers of organisms are present in lesions, culture may be more sensitive than immunohistochemistry for diagnosis.³⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

48.7 THERAPY

No substantial reports have been made on antimicrobial therapy of canine or feline tularemia. In one cat, surgical removal of a localized subcutaneous mass followed by treatment with amoxicillin-clavulanate was curative.³⁵ In people, the aminoglycosides (streptomycin and gentamicin) are currently considered the drugs of first choice, but streptomycin is available only on a limited case-by-case basis.^{12,25} Therefore parenteral gentamicin treatment is the drug of choice (Table 48-1). Precautions should always be taken to monitor renal function during the treatment interval. Tetracycline and chloramphenicol are potential alternative drugs, but relapses occur frequently with their use. Doxycycline would be the preferred tetracycline because of its superior penetration. Historically, both streptomycin and tetracycline have been given successfully in controlled trials of antibiotic prophylaxis in human tularemia.²⁷ Quinolones, such as ciprofloxacin and norfloxacin, may be effective^{29,31}; however, treatment failures have been described.⁷ A significant number of these drugs, such as enrofloxacin, are marketed for animal use. Consult the Drug Formulary, Appendix 8, for dosages and further information on each drug. Because of the potential risk of handling an infected dog or cat, maximal precautions should be used for handling contaminated secretions with gloves and wearing face and eye protection during wound care of hospitalized animals.

Table 48-1 Drug Therapy for Tularemia

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
Gentamicin	B	5 mg/kg	SC, IV, IM	24	7–14
Doxycycline	D	5 mg/kg	PO	12	14
	C	50–100 mg ^c	PO	12	14
Chloramphenicol	C	50 mg/kg	PO, SC, IM	12	14
Enrofloxacin ^d	D	5 mg/kg	PO, SC	12	10
	C	5 mg/kg	PO	24	10

B, Dog and cat; D, dog; C, cat; SC, subcutaneous; IV, intravenous; IM, intramuscular; PO, by mouth.

- a For additional information on selected drugs, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c Do not break or crush tablets because they are irritating to the esophagus. Relapses can occur with bacteriostatic drugs such as doxycycline or chloramphenicol.
- d Other veterinary quinolones such as orbifloxacin, danofloxacin, or marbofloxacin may be substituted at an appropriate dose.

48.8 PUBLIC HEALTH CONSIDERATIONS

In people, tularemia occurs in two main syndromes: ulceroglandular and typhoidal.²⁵ Both syndromes have an incubation period of 2 to 10 days followed by acute onset of high temperature, chills, myalgia, and other nonspecific constitutional symptoms. Ulceroglandular tularemia is characterized by a skin ulcer developing at the

Infectious Diseases of the Dog and Cat, 3rd Edition

portal of infection with associated regional lymphadenomegaly. In typhoidal tularemia, few localizing signs of bacteremia occur, pneumonia is more common, and the case-fatality ratio can exceed 30% if the illness is untreated. Other less common syndromes that occur localized to the site of exposure include oculoglandular (Parinaud's syndrome) from conjunctival exposure, glandular with localized lymphadenomegaly, oropharyngeal (characterized by pharyngitis and tonsillitis), and primary pneumonia from inhalation.

Fig 48-9 Immunohistochemical stain of the spleen of a cat infected with *F. tularensis*. Red areas indicate the location of specific bacterial antigen (peroxidase with hematoxylin counterstain). (Courtesy Dept. of Veterinary Pathology, Kansas State University, Manhattan, Kans.)

In the United States, the incidence of human tularemia is low: fewer than 225 cases annually in the last 10 years.¹ Most cases have resulted from tick-borne infection and to a lesser extent contact with tissues of wild animals such as rabbits. Of the 1041 human cases reported in the southwestern central United States from 1981 to 1987, 17 (1.6%) cases were associated with cat bites and scratches.³² At least 53 additional cat-associated cases and 8 dog-associated cases have been reported in North America, but some of these have not been well substantiated.* Although cat bites have been associated with these human infections, no cases have emerged of human tularemia from nonbite exposure to cats with systemic infection.³⁵

450

451

Exposure to airborne organisms is a particular hazard. Before the availability of live vaccines and protective biosafety hoods, accidental infection of laboratory workers was frequent. Occasional outbreaks, in the general population from incidental aerosol exposure to organisms in the environment, are a reminder of its virulence. Nonlaboratory occupations or avocations that have been associated with an increased risk of infection are farmer, veterinarian, sheep worker, hunter or trapper, and cook or meat handler. Landscapers that whack weeds, mow lawns, and blow leaves have become infected in outbreaks.¹⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

Cat-associated cases usually involved people being bitten or scratched, with the initial lesion typically developing at the trauma site.^{2,6,22,36} Although the cats often have no obvious illness, a common feature has been a history of hunting or eating wild animals, particularly rabbits.

None of the eight dog-associated cases involved bites or scratches. In one case, a young girl developed typhoidal tularemia 3 days after the onset of a vague illness in her pet puppy, which presumably had contact with rabbits.¹⁷ The dog frequently licked the young girl, and its saliva was considered her probable source of infection. In another instance, a family of seven persons staying at a cottage with their dogs during a 1-week period developed pulmonary tularemia.³³ After the dogs finished hunting for rabbits, they would shake the water from their hair when they entered the cottage. The resultant aerosol was considered the most likely source of infection. The dogs never appeared ill but subsequently were found to have antibodies to *F. tularensis*.

Although no cases have been associated with removing ticks from pets, the finding of infected ticks on dogs does indicate a potential hazard.²⁸ See Therapy section earlier in this text for recommendations on handling infected dogs or cats. Owners should be advised concerning risk factors for exposure from their pets.

In Scandinavia, type B infections in people have been more common and have been associated with contaminated water and infected animals that inhabit aquatic environments. Infections with type B in people are less severe and have lower mortality than with type A infections. Most outbreaks have occurred in farmers who processed hay contaminated by dead animals or their secretions, or by contact with mosquitoes. However, epidemiologic assessment of an outbreak showed farming and owning a cat as inherent risk factors.¹¹ Use of protective clothing and facemasks may be needed when working outdoors in endemic areas.

48.8.1 Bioterrorism Risk and Vaccination

Tularemia has been classified as a potential bioterrorism agent, and outbreaks of infection in people or animals must be reported to public health officials. A live attenuated vaccine is available on an investigational basis for people working in high-risk environments such as research laboratories. The vaccine provides partial protection against severe infection in some people and complete protection in others.

49 CHAPTER 49 Actinomycosis and Nocardiosis

David F. Edwards

49.1 ACTINOMYCOSIS

49.1.1 Etiology and Epidemiology

Actinomycosis is a chronic, pyogranulomatous disease characterized by pleural and peritoneal exudates, dense fibrous masses, frank abscesses, and fistulous tracts with draining sinuses. The disease is caused by anaerobic actinomycetes that are endogenous saprophytes of mucous membranes and members of the family Actinomycetaceae. *Actinomyces bowdenii*, *Actinomyces canis*, *Actinomyces catuli*, *Actinomyces hordeovulneris*, *Actinomyces odontolyticus*, *Actinomyces turicensis*,^{67a} *Actinomyces viscosus*, and *Arcanobacterium pyogenes* (formerly *Actinomyces pyogenes*) have been recovered from infected dogs.* *A. bowdenii*, *A. viscosus*, *Actinomyces meyeri*, and *A. pyogenes* have been recovered from infected cats.^{12,13,90,91,108} Anaerobic actinomycetes are part of the normal bacterial flora of the mucous membranes. In addition to streptococci, actinomycetes colonize the peridontal mucosal surfaces and adhere to the tooth surface to form plaque.¹⁴⁵ *A. viscosus*, *A. odontolyticus*, *Actinomyces israelii*, *Actinomyces bovis*, and *Actinomyces naeslundii* have been cultured from the dental plaque of dogs, and *Actinomyces coleccocanis* has been cultured from the canine vagina.⁶⁴ *A. viscosus*, *A. hordeovulneris*, and *Actinomyces denticolens* have been cultured from normal feline gingiva.⁹² These endogenous saprophytes are not normally pathogenic, but if *Actinomyces* species are inoculated into tissues with associated bacteria, an insidious pyogranulomatous disease can develop. (Use of the term “*Actinomyces* species” refers to [1] species currently classified in the genus *Actinomyces* and [2] related *Actinomyces*-like bacteria classified in other genera but that cause the clinical disease recognized as actinomycosis.)

452

Actinomycosis occurs most commonly in young adult to middle-age large-breed male dogs that are used or kept in an outdoor environment.^{58,74} Hunting dogs have the highest prevalence of disease, and males and females seem to be affected equally. Actinomycosis in outdoor dogs is related in large part to their chronic exposure to grasses.^{19,46,47,67,106} Inhaled or ingested florets or awns contaminated in the oropharynx migrate to various sites and act as the nidus of infection. Although infrequently reported in cats, actinomycosis is often attributed to bite wounds.⁹⁰ Because of the difficulty in culturing *Actinomyces* species and their susceptibility to many antibiotics, the true prevalence of actinomycosis in dogs and cats is greater than that suggested by the literature.

* References 13, 24, 37, 43, 49, 63, 65, 67a, 108, 123.

49.1.2 Pathogenesis

Actinomyces species are opportunistic pathogens that depend on mechanical disruption of normal mucosal barriers. Because of the organism's normal habitat, infections must somehow be linked to the mucous membranes, usually the oropharyngeal area. The disease characteristically spreads by direct extension and is unimpeded by normal tissue planes; however, rare instances of hematogenous dissemination occur.^{67a} The most common clinical forms of actinomycosis in cats and dogs involve the cervicofacial region, thorax, abdomen, retroperitoneal space, and subcutaneous tissue.* Infection of the cervicofacial region can develop from bite wounds, perforation of the oropharynx by a foreign body, or chronic gingivitis-periodontitis. Pulmonary

Infectious Diseases of the Dog and Cat, 3rd Edition

infections can develop by aspiration of oropharyngeal material, which may include inhalation of a contaminated grass awn. Preexisting lung disease (e.g., neoplasia) can act as a nidus for infection.⁴² Alternative routes of thoracic infection include involvement of the mediastinum from esophageal perforation and direct extension of cervicofacial or abdominal disease. Intraabdominal actinomycosis develops from swallowed organisms or plant material penetrating the gastrointestinal (GI) mucosa. In people, GI disease, abdominal trauma, or surgery often precedes infection. Penetration of the GI tract by a bullet or other foreign bodies, including plant material, also increase the risk of infection for animals. Like thoracic infections, abdominal involvement can occur by direct extension. Infection of the retroperitoneal space in dogs is often associated with grass foreign bodies. Theoretically, contaminated grass florets or awns migrate to the space by migrating through the lung and up the crus of the diaphragm to its dorsal attachment, or by perforating the intestinal wall and migrating via the mesentery to its dorsal attachment. Actinomycosis of the limbs is caused by bite wounds, foreign bodies, and lacerations contaminated by licking. Infection of the subcutaneous tissue in dogs usually represents an extension of cervicofacial, thoracic, or retroperitoneal disease, whereas in cats it is caused by bite wounds. Central nervous system (CNS) infections develop from hematogenous or lymphatic dissemination from a primary site or direct extension from a contiguous infection.

Actinomycosis is characteristically a polymicrobial infection, and the pathogenicity of *Actinomyces* species is dramatically increased in mixed infections. The associated bacteria are commensal organisms from the oral cavity or intestinal tract that produce and maintain an anaerobic tissue environment. Inoculation of pure cultures of *Actinomyces* species or the associated bacteria alone often do not produce infection. *Actinomyces* species with fimbriae bind to specific cell surface receptors on other bacteria. This coaggregation markedly inhibits neutrophil phagocytosis of and bactericidal activity on the bacterial complex.¹⁰⁷ If not bound to other bacteria, actinomycetes bind to specific receptors on neutrophils, initiating phagocytosis and degranulation. Additionally, *Actinomyces* species induce neutrophil chemotaxis, activate macrophages, and stimulate B-lymphocyte hyperplasia. These bacterial-cellular interactions produce the characteristic actinomycosis lesion—a dense mat of *Actinomyces* species and associated organisms surrounded by neutrophils, macrophages, and plasma cells. Proteolytic enzymes from the associated bacteria, macrophages, and degranulated neutrophils destroy connective tissue, facilitating extension of the disease through normal tissue planes.¹⁴⁵

49.1.3 Clinical Findings

49.1.3.1 Dog

Cervicofacial actinomycosis produces acute to chronic subcutaneous soft tissue swelling in the head or neck region.^{37,42,106,128} The lesion can be fluctuant or firm, may be indurated, and can be ulcerated or have draining sinuses. The mandible, submandibular region, and ventral or lateral cervical area are most frequently affected, but infections involving the face, retrobulbar space, and temporal area have been reported. Radiographically, adjacent bone can have periosteal new bone formation, and a chronic infection may be characterized by osteomyelitis. Ultrasonography and magnetic resonance imaging can be used to identify linear grass awn foreign bodies.^{46a,124a} Material aspirated from fluctuant masses or discharged from sinuses appears serosanguineous to purulent and may contain macroscopic, yellow-tan granules (i.e., *sulfur granules*), which are small, soft macroscopic colonies of actinomycetes that are often present in exudates or infected tissue. The term *sulfur granule* was derived from the frequently seen yellow pigmentation of the granule; however, granule color can vary from white to tan to gray (Fig. 49-1). Aspiration of firm lesions may yield only a few drops of blood.

Infectious Diseases of the Dog and Cat, 3rd Edition

Actinomycosis involving the thoracic or abdominal cavity is characteristically chronic and progressive; weight loss, often severe, and fever are the most common clinical signs. *Thoracic actinomycosis* may be limited to the lung parenchyma but can involve multiple structures within the thorax, including the mediastinum, pleura, heart, and chest wall.* Other clinical features include cough, tachypnea, dyspnea, decreased lung sounds (from empyema or a mass lesion), and subcutaneous soft tissue masses on the lateral thorax. Thoracic wall masses often develop a draining sinus. Radiographically, lung disease appears as alveolar and interstitial infiltrates with consolidation. Variable findings include pleural thickening, pleural effusion (often loculated to one side), pericardial effusion, widening of the mediastinum, mass lesions, and periosteal new bone formation or osteomyelitis involving adjacent ribs, vertebral bodies, or sternebrae. Clinical features of *abdominal actinomycosis* include palpable masses and abdominal distention (effusion).^{29,43,49,58}

Subcutaneous masses, which may have draining sinuses, are rarely present unless the abdominal disease develops from an extension of thoracic or retroperitoneal infections. Radiographic manifestations include variable amounts of peritoneal effusion and mass lesions that incorporate or displace adjacent structures. Pleural, pericardial, and peritoneal effusions resemble the exudate from cervicofacial abscesses.

Fig 49-1 Thoracic exudate in Petri dish containing numerous macroscopic sulfur granules. (Courtesy David F. Edwards, University of Tennessee, Knoxville, Tenn.)

Retroperitoneal actinomycosis is characterized by back pain and rear leg paresis or paralysis.^{37,47,67,77} A subcutaneous mass with a draining sinus involving the caudal thorax or flank area is often present. Radiographic findings include periosteal new bone formation involving the ventral aspects of two or three adjacent vertebral bodies (usually T-13 through L-3); involvement of disk spaces is uncommon (Fig. 49-2). Chronic disease may cause the vertebral bodies to develop osteomyelitis and compression fractures. This

Infectious Diseases of the Dog and Cat, 3rd Edition

finding contrasts with diskospondylitis caused by embolic spread of bloodborne bacteria or fungi to the disk space (see [Chapters 40, 64, and 86](#)).

Cutaneous-subcutaneous actinomycosis is characterized by a soft to firm mass, which may have a draining sinus.^{37,47,74,106,128} These infections are typically located in the head and neck area, lateral thoracic wall, and flank region and are usually extensions of cervicofacial, thoracic, or retroperitoneal actinomycosis.

Rare cases of actinomycosis involving the extremities and CNS have been reported. Lameness, mass lesions with draining sinuses, and periosteal new bone formation are characteristic of limb involvement.^{20,58}

Actinomycosis of the brain is rare,^{128,5,34} whereas involvement of the spinal cord is a common sequela to subvertebral infections.^{43,67,77} Clinical findings associated with brain infections are nonlocalizing and include altered behavior, decreased consciousness, neck pain, ataxia, abnormal reflexes, and seizures. With spinal cord involvement, pain, paresis, paralysis, and abnormal reflexes are noted, and radiographic evidence of a bony change in adjacent vertebral bodies is present. Cystitis in dogs has been associated with *Arcanobacterium pyogenes* and a *Nocardia*-like organism, which most likely represents *A. turicensis*, a common isolate from wogenital tract infections.^{13,66,68,117}

Fig 49-2 Spinal radiograph of an 8-year-old pointer with retroperitoneal actinomycosis. Periosteal new bone growth (*arrows*) is present on ventral aspect of vertebral bodies of L-2 and L-3. (Courtesy David F. Edwards, University of Tennessee, Knoxville, Tenn.)

* References 18, 28, 37, 43, 46, 47, 58, 89, 115, [124](#), 128.

49.1.3.2

Cat

Pyothorax and subcutaneous bite wound abscesses are the most common disorders in cats from which *Actinomyces* species are isolated.^{90,91} The abscesses have a malodorous, yellow to sanguineous exudate without a granulomatous mass, and the *Actinomyces* species is always mixed with two to five other pathogens. Actinomycosis as described in the dog has been reported infrequently in cats. The feline cases

Infectious Diseases of the Dog and Cat, 3rd Edition

have involved the cervicofacial region,^{30,84,147} thoracic cavity,⁶⁰ and subcutaneous tissue with extension to the spinal canal.^{12,127} Otitis external secondary to *A. pyogenes* has been reported in a cat.¹³

49.1.4 Diagnosis

49.1.4.1 Clinical Laboratory Findings

Hematologic test results in animals with actinomycosis vary according to the location and duration of disease. Animals with focal lesions (e.g., cervicofacial and limb infections) may have few abnormal results, whereas animals with more extensive, chronic disease have mild to moderate nonregenerative anemia, leukocytosis with a left shift and monocytosis, hypoalbuminemia, and hyperglobulinemia (sometimes marked). Dogs with body cavity effusions may be hypoglycemic. Aspirates of abscesses or effusions, tracheal lavages, and sinus discharges are suppurative to pyogranulomatous, whereas aspirates of firm masses may reveal only blood. In some specimens, especially those from effusions, sulfur granules are visible macroscopically (see Fig. 49-1). Microscopically, mixed bacterial populations containing rods and cocci are common. The actinomycetes appear individually or in dense aggregates (sulfur granules) as gram-positive, non-acid-fast filamentous organisms that are occasionally branched (Fig. 49-3). *Nocardia* species and *Filifactor villosus*—gram-positive filamentous rods can be confused with *Actinomyces* species.^{91,135}

Fig 49-3 Smear of thoracic fluid. Dense mat of infrequently branched, filamentous rods (i.e., sulfur granule). Note presence of other bacterial species (×198). (Courtesy David F. Edwards, University of Tennessee, Knoxville, Tenn.)

453

The disease is confirmed by culture of the organism, but frequently culture results are negative or contain only associated bacteria. *Actinomyces* species either are facultative (*A. canis*, *A. catuli*, *A. coleocanis*, *A. bowdenii*, *A. denticolens*, *A. hordeovulneris*, *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, *A. pyogenes*) or obligate (*A. bovis*, *A. israelii*, *A. meyeri*) anaerobes.^{16,63-65,108} Specimens should be collected and processed anaerobically and cultured on blood agar or enriched thioglycolate media in the presence of 5% to 10% carbon dioxide. Species that are facultatively anaerobic are variably aerotolerant and can grow aerobically. *A. viscosus* actually grows best in aerobic conditions. All species cultured aerobically require carbon dioxide, except *A. bowdenii*, *A. naeslundii*, and *A. odontolyticus*.⁶¹

Growth of *Actinomyces* species can be observed within 48 hours but usually requires 5 to 7 days. It may be necessary to hold plates 2 to 4 weeks. Colonies on blood agar are flat to convex, circular with entire or irregular margins, and translucent to opaque and white; surfaces are smooth and moist or rough (*bread crumb* or *molar tooth* surface). Some strains of *A. israelii* produce aerial filaments, resulting in a powdery, or cotton ball, appearance. Microscopically *Actinomyces* species are gram-positive, non-acid-fast short rods and filaments. The filaments are less than 1 μm wide, vary considerably in length, may branch, and can stain irregularly, producing a beaded appearance.^{18,29,43,58,74} *Actinomyces* species are heterogeneous, and species identification using traditional biochemical tests is difficult.¹²⁰ Results of 16S rRNA gene sequence analysis of previously identified species indicates that several genera in addition to *Arcanobacterium* and *Actinobaculum* will emerge from the species now classified in the genus *Actinomyces*.^{31,56,112} Variants of *A. hordeovulneris* that are cell wall deficient have been produced in culture, suggesting that L forms of *Actinomyces* species may be associated with clinical disease; however, because of special culture requirements, these variants would be isolated infrequently.²³

Actinomycosis is characteristically a mixed bacterial infection.* Three to five associated bacteria are typically recovered from properly handled specimens. The most commonly isolated organisms are resident flora of the oral cavity or intestinal tract and include *Bacteroides* species, *Corynebacterium* species, *Escherichia coli*, *Eubacterium* species, *Fusobacterium* species, *Pasteurella multocida*, *Peptostreptococcus* species, *Staphylococcus aureus*, and *Streptococcus* species. Most of the associated bacteria are facultative or obligate anaerobes, therefore isolation requires appropriate specimen handling. Unfortunately, the growth of a mixed microflora can impair the isolation of *Actinomyces*.⁶¹

Because *Actinomyces* species are sensitive to many antibiotics, the treatment of animals before obtaining specimens for culture can prevent recovery of the organisms. This fact, compounded by improperly handled specimens and polymicrobial growth, accounts for the frequent failure of *Actinomyces* isolation from infected animals. The diagnosis is often based on the cytologic or histologic identification of the organism in specimens from animals with appropriate clinical signs. Because *Actinomyces* is a commensal oral bacteria, it is commonly swallowed, inhaled, and transferred by licking, therefore culture of the organism from the airways, GI tract, or skin does not necessarily constitute infection.

* References 19, 47, 58, 74, 90, 91, 134.

Infectious Diseases of the Dog and Cat, 3rd Edition

49.1.5 Pathologic Findings

Actinomycosis is characterized by a poorly defined, often indurated mass that incorporates adjacent structures.[†] The mass may contain one or more pockets of a reddish-brown exudate. Fistulas and sulfur granules may be found. Thoracic and abdominal infections produce a diffuse, red, velvety to granular thickening of the parietal pleura and peritoneum and omentum. The visceral pleura and peritoneum may be less affected. A variable amount of a reddish-brown exudate that may contain sulfur granules is present. Lung involvement is usually localized and may appear as a consolidation or mass; infrequently, multiple pulmonary nodules are present. Masses can affect multiple internal structures (e.g., heart, mediastinum, lung, diaphragm, and chest wall) and produce an external subcutaneous swelling that may have a draining sinus. With abdominal disease, only one organ may be affected (e.g., liver), but typically a mass or masses involve multiple adjacent structures.^{29,43,49} Subcutaneous masses may be ulcerated and in dogs are usually an extension of cervicofacial, thoracic, or retroperitoneal disease.^{37,47,67}

The histologic reaction to *Actinomyces* species infection is characterized by a core of neutrophils encapsulated by fibrosing granulation tissue. The granulation tissue contains macrophages, plasma cells, and lymphocytes in a dense, fibrous tissue matrix. The centrally located actinomycotic (sulfur) granule or grain can be very difficult to find, so multiple tissue sections may be needed to confirm the diagnosis. When associated with appropriate clinical signs, identification of true actinomycotic granules is diagnostic of actinomycosis. In tissue sections stained with hematoxylin and eosin (H and E), the granules appear as round, oval, or scalloped amphophilic solid masses with an outer basophilic band (Fig. 49-4, A). The granules vary in size (from 30 to 3000 µm in diameter) and often are rimmed by partially confluent radiate, eosinophilic serrate, or club-shaped structures (i.e., the Splendore-Hoeppli phenomenon). Neutrophils frequently contact or appear enmeshed in this material. Individual actinomycete filaments are not delineated by H and E stain or Gridley's fungal or periodic acid-Schiff reactions, whereas Gram staining of tissues (i.e., the Brown-Brenn procedure) reveals clumps of tangled, intermittently branched, thin (less than 1 µm in diameter) filaments that are gram-positive and slightly beaded (Fig. 49-4, B). Gram-positive or gram-negative nonfilamentous bacteria can be mixed with the *Actinomyces* species. *Actinomyces* species are non-acid-fast when stained by the Fite-Faraco modification of the Ziehl-Neelsen technique, which uses a weaker decolorizing agent of 1% sulfuric or 1% hydrochloric acid. With the rare exception of some *Nocardia* species, other fungi and bacteria that produce tissue granules can be reliably distinguished from *Actinomyces* by tinctorial and morphologic properties.²⁷ Features of nocardiosis that distinguish it from actinomycosis are listed in Table 49-1.

† References 28, 29, 43, 60, 89, 128, 134.

49.1.6 Therapy

Successful treatment of actinomycosis involves prolonged administration of antibiotics; the role of surgery varies with the form of the disease. Large doses of penicillin given for prolonged periods (weeks to months) is the treatment of choice (Table 49-2).⁸¹ No strains of *Actinomyces* species have shown in vitro resistance to easily attainable serum concentrations of penicillin, and acquired resistance in vivo has not been confirmed. Poor drug penetration of the dense granulomatous tissue reaction necessitates the prolonged, high-dose therapy. A minimal dose of penicillin G (benzyl penicillin) or penicillin V (phenoxymethyl penicillin) of 40 mg/kg every 8 hours is recommended.⁴³ Units of penicillin equivalency per milligram depend on the formulation (see Appendix 8). The therapeutic advantage of initial parenteral administration is questionable, therefore if the animal is stable clinically, oral therapy can be started from the outset.^{43,105} Because food reduces the

Infectious Diseases of the Dog and Cat, 3rd Edition

absorption of most penicillins, medication should be given 1 hour before or 2 hours after feeding. Therapy must be extended significantly (weeks to months) beyond resolution of measurable disease to prevent relapse; in some cases, treatment can exceed 1 year.^{43,58} Drugs other than penicillin that are effective against most *Actinomyces* species include erythromycin, clindamycin, ampicillin, tetracycline, minocycline, doxycycline, chloramphenicol, imipenem, and first-generation cephalosporins and ceftriaxone.^{81,123,146} Anecdotal success with ciprofloxacin was reported in a human patient with recalcitrant actinomycosis of 20 years' duration;⁹⁴ however, recently described *Arcanobacterium bernardiae* and *Actinomyces neuui* are resistant to ciprofloxacin, and in vitro resistance to fluorinated quinolones was reported for an *Actinomyces* species isolate from a dog with thoracic disease.^{16,41} Oxacillin, dicloxacillin, cephalexin, metronidazole, and aminoglycosides have poor in vitro activity against most *Actinomyces* species; however, *A. pyogenes* is sensitive to aminoglycosides (other than streptomycin) but resistant to tetracycline, minocycline, and doxycycline.⁵⁵ Poor response to appropriate doses of penicillin may be attributable to poor surgical drainage and failure to eliminate associated bacteria.⁸¹ Infections by these organisms usually resolve with penicillin, but on occasion they require broader spectrum antibiotics during the initial treatment period followed by long-term administration of penicillin. Cats with pyothorax or subcutaneous abscess that have not developed a granulomatous tissue reaction often can be cured with drainage and a shorter duration of antibiotic treatment.

Fig 49-4 **A**, H and E stained section of abdominal mass from 5-year-old neutered female boxer dog. Actinomycotic tissue granule is surrounded by neutrophils. Encapsulating fibrous tissue has mononuclear cell infiltrate. (The long dimension of the granule measures 695 μm ; $\times 13.2$). **B**, Tissue section (Gram stain, Brown-Brenn procedure) of intrathoracic mass from 4-year-old German shorthaired pointer. Actinomycotic tissue granule showing infrequently branched, filamentous rods characteristic of *Actinomyces* organisms ($\times 132$). (**A**, Courtesy David F. Edwards, University of Tennessee, Knoxville, Tenn.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 49-1 Comparison of Actinomycosis Versus Nocardiosis

ACTINOMYCES SPECIES	NOCARDIA SPECIES
Culture 1. Facultative or obligate anaerobe 2. Fastidious growth requirements; often not cultured 3. Two to five associated microbes usually recovered	1. Aerobe 2. Usually cultured 3. Sole isolate unless from contaminated sample (e.g., tracheal wash, ulcerated skin)
Staining Characteristics 1. Irregular staining that can produce slight beading 2. Gram-positive and non-acid-fast using Fite-Faraco modification of Ziehl-Neelsen technique	1. Irregular staining that can produce marked beading 2. Gram-positive and partially acid-fast using Fite-Faraco modification of Ziehl-Neelsen technique
Cytopathologic Characteristics 1. Suppurative to pyogranulomatous inflammation with a mixed bacterial population; macroscopic and microscopic dense mats of long filamentous bacteria often present (see Fig. 49-3)	1. Suppurative to pyogranulomatous inflammation; long filamentous bacteria typically present singly or in loose aggregates (see Fig. 49-6); infrequently macroscopic and microscopic dense mats of long filamentous bacteria present
Histopathologic Characteristics 1. Pyogranulomatous inflammation with marked encapsulating fibrosis (see Fig. 49-4) 2. Variable presence of tissue granules (30–3000 mm diameter)	1. Pyogranulomatous inflammation; significant fibrosis present only in chronic skin infections (see Fig. 49-7) 2. Granules present only in skin infections (15–200 mm diameter)
Clinical Disease 1. In adult outdoor dogs (especially hunting breeds); with bite wounds and pyothorax in cats 2. Direct spread to adjacent structures 3. Sensitive to high doses of penicillin 4. Low mortality	1. In dogs younger than 2 years old; from fight wounds in cats 2. Hematogenous spread; can see lesions at noncontiguous sites 3. Variable sensitivity to sulfonamides 4. Moderate to high mortality

Table 49-2 Drugs Used to Treat Actinomycosis in Dogs and Cats

DRUG^a	SPECIES	DOSE^b	ROUTE	INTERVAL (HOURS)
Penicillin G	B	100,000 U/kg	IV, IM, SC	6–8
Penicillin G ^c	B	40 mg/kg ^d	PO	8
Penicillin V	B	40 mg/kg ^d	PO	8
Clindamycin	B	5 mg/kg	SC	12
Erythromycin	B	10 mg/kg	PO	8
Chloramphenicol	D	50 mg/kg	PO, IV, IM, SC	8
	C	50 mg/kg	PO, IV, IM, SC	12
Rifampin	D	10 mg/kg	PO	12
Minocycline	B	5–25 mg/kg	IV, PO	12
Ampicillin (amoxicillin) ^c	B	20–40 mg/kg	IM, SC, PO	6

B, Dog and cat; D, dog; C, cat; IV, intravenous; IM, intramuscular; SC, subcutaneous; PO, by mouth.

a See Appendix 8 for more information on these drugs.

b Dose per administration at specified interval. For duration, see text.

c Give at least 1 hr before or 2 hr after feeding to facilitate GI absorption.

d Minimum recommended dose (see text); 1 mg = 1600 U (see Appendix 8).

Infectious Diseases of the Dog and Cat, 3rd Edition

Surgery has a controversial role in the treatment of actinomycosis. Draining of abscesses and effusions (thoracic, abdominal, and pericardial) should always be used as an adjunct to antibiotic treatments.^{58,60,115} Continuous suction and intermittent drainage techniques have been used for thoracic effusions in dogs.^{46,134} Drain tubes are removed when the purulent exudate changes to a serosanguineous transudate, usually within 4 to 10 days. Daily lavage with fluids containing crystalline penicillin G may be beneficial. Using sodium penicillin rather than potassium penicillin in the lavage fluid prevents the development of cardiotoxicity from hyperkalemia. (Crystalline potassium penicillin G contains 1.7 mEq potassium per 10⁶ U.) Complications of drainage include pneumothorax and subcutaneous abscess formation at the drain tube insertion site. Animals not responding to drainage and appropriate antibiotic therapy warrant exploratory surgery.^{46,115,134} In animals with pulmonary abscesses, diseased lung lobes often require removal. The characteristic invasive fibrotic lesions obliterate tissue planes, preventing conservative dissection, and the tissue is well vascularized, therefore moderate to severe bleeding is common. With diffuse disease involving body cavities, tissue resection should be restricted to decrease the chance of death. In dogs with solitary masses involving the thoracic and abdominal walls, radical surgical excision has a high cure rate, although repeat surgeries may be needed.⁴⁶ The masses often can be reduced and better defined by an initial period of antibiotic therapy. Frequently, grass florets or awns are found in these lesions and during surgical exploration of diseased retroperitoneal regions.^{46,46a,67,124a} Surgery should never be performed in lieu of and should always be followed by appropriate antibiotic therapy.

Appropriate treatment of dogs with actinomycosis, which can involve extremely prolonged use of antibiotics and surgery, results in a cure rate of greater than 90%.^{43,46,58} Because of the infrequent documentation of actinomycosis in cats, a meaningful cure rate is not available, but it is likely similar to the cure rate in dogs.

49.1.7 Public Health Considerations

No reports exist of actinomycosis being transmitted from clinically infected animals to humans or to other animals; however, humans bitten by dogs, cats, or other people can develop actinomycosis.¹¹³ Nevertheless, animal care workers handling infected tissues or discharge should wear protective gloves to avoid inadvertent contact by inoculation or through damaged skin.

49.2 NOCARDIOSIS

49.2.1 Etiology and Epidemiology

Nocardiosis is a suppurative to granulomatous, localized or disseminated bacterial infection caused by aerobic actinomycetes that are members of the family Nocardiaceae.^{10,11} *Nocardia asteroides* is the most commonly isolated species in dogs and cats, but infections by *Nocardia brasiliensis* (in the dog and cat), *Nocardia* 456
otitidiscaviarum (in the dog and cat), *Nocardia nova* (in the cat), and *N. africana* (in the cat) have been 457
reported.* As historically defined, *N. asteroides*,^{126,116} *N. brasiliensis*,¹³⁶ *N. nova*,³³ *N. otitidiscaviarum*^{108a}
and *Nocardia transvalensis*¹⁴² consist of several subtypes and species. Recent publications cite approximately 34 valid species of *Nocardia*; to date, at least 20 species have been implicated in human infections. It is certain previous reports of nocardiosis in dogs and cats understate the number of species producing disease. These aerobic actinomycetes are ubiquitous soil saprophytes that degrade organic matter and are found in soil, in water, and on plants.^{10,99} Infections are considered opportunistic, occurring by either inhalation of organisms or inoculation through puncture wounds.

Infectious Diseases of the Dog and Cat, 3rd Edition

In a survey of 53 dogs with nocardiosis, males were infected three times more frequently than females; 65.4% of the dogs were younger than 1 year, 82.7% were younger than 2 years, and only 7.8% were older than 6 years; 26.9% had an underlying condition, most often canine distemper.¹¹ Apparently in dogs, like in people, predisposing factors (i.e., diseases) increase susceptibility to nocardiosis. Approximately 40% of people with nocardiosis have primary disorders that involve immunosuppressive drug therapy, obstructive pulmonary disease, metabolic disorders (e.g., hyperadrenocorticism, diabetes mellitus), neoplasia (lymphosarcoma, leukemia), immunologic disease (systemic lupus erythematosus, dysgammaglobulinemia), or infectious diseases (e.g., acquired immunodeficiency syndrome).^{10,99} In 20 reported cases of feline nocardiosis, 15 involved males and 4 involved females.[†] Ages ranged from 2 to 15 years (with a median age of 7 years). Fourteen of the cats had draining wounds or abscesses that were associated with scratches or bite wounds.

* References 2, 11, 59, 62, 93.

† References 2, 3, 6, 9, 26, 38, 59, 62, 78, 93, 95, 102, 109, 131, 141.

49.2.2 Pathogenesis

Similar to the systemic mycoses, pulmonary nocardiosis probably results from inhalation of soil organisms. Nocardial lesions develop in alveolar spaces and frequently erode into blood vessels, resulting in systemic spread of the disease. Secondary lesions from systemic spread can develop in any tissue. Involvement of contiguous structures within the thorax (e.g., pleura, mediastinum, pericardium) is also common. Localized cutaneous, subcutaneous, and regional lymph node infections result from inoculation through a puncture wound (e.g., bite, scratch, foreign body). Other solitary extrapulmonary sites of infection are likely caused by localization from a transient bacteremia. The primary source may be an inapparent pulmonary infection.^{10,99}

Pathogenicity of *Nocardia* species is influenced by the strain and growth phase of the organism and host susceptibility. Normal host response to infection is characterized by an initial neutrophil mobilization that may inhibit growth but not kill the organism. Subsequent cell-mediated immunity consisting of activated macrophages and T lymphocytes is normally bactericidal. Diminished host resistance is a primary factor in nocardiosis, but not all diseased animals have identifiable predisposing conditions. Virulent strains of *Nocardia* are facultative intracellular pathogens that inhibit phagosome-lysosome fusion, neutralize phagosomal acidification, resist oxidative burst, and alter lysosomal enzymes within neutrophils and macrophages. These effects are partly related to the content and structure of mycolic acids within the bacterial cell wall, which vary among strains and during the growth phase. Some strains exhibit organ-specific tropism (e.g., brain), and the filamentous, logarithmically growing organisms are 10 times more virulent than the coccoid stationary-phase cells.^{10,99}

49.2.3 Clinical Findings

49.2.3.1 Dog

Pulmonary nocardiosis can have a peracute onset characterized by inspiratory dyspnea, hemoptysis, hypothermia, collapse, and death⁸⁵; however, subacute to chronic clinical symptoms are more characteristic.^{1,26,36,76,96} The signs are often similar to those of distemper and include mucopurulent oculonasal discharge, anorexia, weight loss (often emaciation), cough, dyspnea, diarrhea, and hyperthermia. Lung sounds may be increased (from bronchopneumonia) or decreased (from a mass lesion or empyema).

Infectious Diseases of the Dog and Cat, 3rd Edition

Coinfection by the canine distemper virus is commonly reported.¹¹ The radiographic appearance of lesions varies and includes multiple, diffuse pulmonary nodules, intrapulmonary or extrapulmonary solitary masses, focal or diffuse bronchointerstitial to alveolar infiltrates, lobar consolidations, pleural effusions, and often, dramatic hilar lymphadenopathy (Fig. 49-5).

Systemic, or disseminated, nocardiosis, defined by lesions at two or more noncontagious sites within the body, is typically associated with pulmonary disease and rarely develops without obvious associated pulmonary disease.* The most frequently involved extrathoracic organs are skin and subcutaneous tissue, the kidney, the liver, the spleen, lymph nodes, the CNS, bone, and joints. The cutaneous-subcutaneous lesions are characterized by firm to fluctuant swellings that may ulcerate or develop fistulous tracts through which a reddish-brown exudate is discharged. Involvement of the liver, the spleen, and lymph nodes is detected because of organomegaly. CNS lesions may cause seizures. Bone or joint infection results in swelling and lameness; radiographic findings include soft tissue swelling, bone lysis, and periosteal new bone growth.

Solitary extrapulmonary nocardiosis develops infrequently and usually occurs as a cutaneous-subcutaneous abscess⁸ or an actinomycotic mycetoma.^{20,119} A case of humeral osteomyelitis has been reported.⁴⁰ Mycetoma is a localized, subcutaneous granulomatous tumor that contains organized aggregates (grains or granules) of free-living or exogenous, geophilic actinomycetes (actinomycotic mycetoma) or fungi (eumycotic mycetoma). Mycetomas usually develop on extremities, may involve underlying bone, and typically form abscesses that result in fistulas to the skin. Because *Actinomyces* is endogenous, tumorous infections of subcutaneous tissues are not classified as mycetomas. *Nocardia* infections have been reported in 10 dogs with thoracolumbar vertebral osteomyelitis and in one dog with cystitis⁶⁶; however, many of these dogs were probably infected with *Actinomyces* species (see Actinomycosis, Clinical Findings, in this chapter).^{17,103,122,125}

* References 1, 8, 72, 73, 76, 96, 114, 121, 129.

49.2.3.2

Cat

The clinical forms of feline nocardiosis (pulmonary, systemic, and solitary extrapulmonary) are similar to those described in the dog; however, in cats, cutaneous-subcutaneous disease (abscesses and actinomycotic mycetomas) is the most common clinical form. Of 20 reported cases of nocardiosis, 14 cats had cutaneous-subcutaneous lesions involving the extremities,[†] inguinal area,^{5,59,62,102} and neck.^{23,62} Five cats had pulmonary disease (nodules or empyema),^{3,6,78,95,109} one had peritonitis,¹³¹ and five had systemic nocardiosis.^{2,3,59,95,141} All those with systemic disease had a primary cutaneous-subcutaneous lesion. Macroscopic sulfur granules were noted in the exudate of five cats (representing all three forms of clinical disease).^{26,38,62,131}

457

† References 72, 38, 62, 93, 95, 141.

49.2.4 Diagnosis

49.2.4.1 Clinical Laboratory Findings

Animals with nocardiosis have nonregenerative anemia, neutrophilic leukocytosis with a left shift, monocytosis, and hyperproteinemia. Hypercalcemia associated with granulomatous disease has been reported.¹⁰² Pleural effusions, bronchial lavages, and aspirates of abscesses are suppurative to pyogranulomatous. Gram-positive, partially or weakly acid-fast, beaded, branching filamentous organisms are often observed individually or in loose aggregates (Fig. 49-6). Macroaggregates (i.e., sulfur granules) have been noted infrequently in effusions. Unlike actinomycosis, mixed bacterial populations from deep tissue sites are rare and probably caused by contamination of the sample (e.g., bronchial lavage, ulcerated skin abscess).^{1,8,76,96}

Infectious Diseases of the Dog and Cat, 3rd Edition

49.2.4.2 Bacterial Isolation and Identification

The presence in clinical specimens of a gram-positive, partially acid-fast, beaded, branched filamentous organism 0.5 to 1 μm in diameter warrants specific therapy for nocardiosis, but the diagnosis is confirmed by culture of the organism. *Nocardia* species grow aerobically at a wide temperature range on simple media (e.g., Sabouraud's glucose agar, blood agar). Growth is enhanced by 10% carbon dioxide, modified Thayer-Martin medium and buffered charcoal-yeast extract agar but is retarded by inhibitory medium used for fungal isolation. Organisms are usually recovered in pure cultures, and colonies are often visible after 2 days. However, 2 to 4 weeks of incubation may be necessary, especially if samples contain multiple bacterial species (e.g., bronchial lavage) or are from animals receiving antibiotics. Colonies can be smooth and moist or rugose with a powdery surface from aerial filaments. Because most *Nocardia* species produce carotenoid-like pigments, colony color varies (cream, yellow, orange, pink, or red).^{10,82,99} Microscopically, *Nocardia* species grown on solid media appear as branched filaments that fragment into pleomorphic, rod-shape, or coccoid elements. *Nocardia* species are gram-positive and variably acid-fast. In clinical specimens or primary isolates, *Nocardia* species are often partially acid-fast, but a Fite-Faraco modification of the Ziehl-Neelsen technique decolorized with 1% sulfuric or 1% hydrochloric acid must be used. Not all pathogenic strains of *Nocardia* species are acid-fast—a characteristic that may disappear after subculture.^{10,82,99}

Fig 49-6 Impression smear of chronic (15 months duration), ulcerated cutaneous lesion on lateral thorax of 3-year-old female domestic shorthaired cat. Loose aggregate of infrequently branched, filamentous rods with beading from irregular staining is typical of *Nocardia* organisms ($\times 330$). (Courtesy David F. Edwards, University of Tennessee, Knoxville, Tenn.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Identification of the species of *Nocardia* isolates is important for prediction of antimicrobial susceptibility. Traditionally, species have been distinguished by phenotypic features, including growth characteristics and antibiotic susceptibility patterns; however, modern molecular methods have provided a more reliable and rapid means of speciation.^{32,75,138} Restriction fragment length polymorphism (RFLP) analysis of polymerase chain reaction (PCR) products from the 16S rRNA gene identifies most pathogenic *Nocardia* organisms at a level of therapeutic relevance, but ultimate differentiation of closely related *Nocardia* species may require RFLP analysis of *hsp* gene products, 16S rRNA and *hsp* gene sequencing, or DNA-DNA hybridization.^{33,116,142} L-form *Nocardia* spp., cell wall-deficient variants, have been associated with clinical disease in people and a dog.²² These bacteria require special media for isolation and culture (see [Chapter 33](#)).

458

459

Pathogenic *Nocardia* species are not common laboratory contaminants, therefore the isolation of a single colony from a closed lesion is significant. Because *Nocardia* organisms are ubiquitous in soil and in certain circumstances may act as respiratory saprophytes, the isolation of small numbers of organisms from ulcerated skin lesions or the respiratory tract must be interpreted in conjunction with clinical signs.^{10,82,99}

49.2.5 Pathologic Findings

Nocardiosis is characterized by suppurative necrosis and abscess formation and infrequently produces granulomas. The gross lesions on internal organs typically are numerous small (1 mm) to large (1 cm), discrete to coalescing, raised white or gray-white nodules.^{72,114,121,129} The nodules are usually subserosal and when cut appear caseous to purulent. Affected lung tissue may appear congested. Lymph nodes are enlarged, often massively, and are firm to fluctuant with a caseous to purulent core.^{36,76,114} A reddish-brown exudate may be present in the pleural or peritoneal space or within abscesses.^{1,8,128} Yellow granules in the exudate have been noted.^{76,131}

The histologic reaction to nocardial infection is characterized by a central region of necrosis and suppuration surrounded by macrophages, lymphocytes, and plasma cells.^{114,121,129} Clusters of epithelioid macrophages and multinucleated giant cells may be observed. Except with some skin infections, fibrous tissue is usually poorly structured, producing thin or incomplete encapsulation of the lesion. In chronic cutaneous-subcutaneous infections, pyogranulomatous foci may be interspersed within a dense fibrous tissue matrix.^{20,36}

Nocardial organisms are usually present and often abundant in the necrotic and suppurative tissue reactions. Gram staining of tissue (e.g., the Brown-Brenn procedure) is best for seeing the filaments, but tissues can also be stained by methenamine silver preparations, especially with prolonged silver nitrate exposure (i.e., 80 to 100 minutes). *Nocardia* filaments are not visible in tissue sections stained with H and E or with Gridley's fungal or periodic acid-Schiff reactions. The organisms are characteristically but not invariably partially acid-fast when a weak decolorizing solution is used (i.e., 1% sulfuric or 1% hydrochloric acid). *Nocardia* species appear as beaded, branching filaments that are 10 to 30 μm or more long and 0.5 to 1.0 μm wide. The filaments usually appear individually or in tangled, loose aggregates. In chronic skin infections, tissue granules characterized by colonies arranged in large, rosette-like arrays have been reported ([Fig. 49-7](#)). In human nocardiosis, tissue granules are uncommon; when present, the granules are small (15 to 200 μm), usually not associated with the Splendore-Hoeppli phenomenon, and usually produced in chronic skin infections by *N. brasiliensis*.

Infectious Diseases of the Dog and Cat, 3rd Edition

49.2.6 Therapy

Sulfonamides, including trimethoprim-sulfonamide combinations, are the primary drugs for treating nocardiosis (Table 49-3). Most *Nocardia* species, with the possible exception of *N. otitidiscaviarum*, are susceptible to sulfonamide therapy, but treatment must be continued for a prolonged period. From 1 to 3 months is recommended in people with cutaneous infections, up to 6 months for uncomplicated pulmonary infections, and 12 months or longer for systemic infections or infections in those who are immunocompromised. Clinical improvement should be observed within 7 to 10 days of starting treatment. Abscesses or empyema usually must be surgically drained to cure the patient.^{82,99}

Antibiotics in addition to or other than sulfonamides may be needed because not all *Nocardia* isolates are sensitive to sulfonamides, in vitro susceptibility may not be associated with clinical response, and resistance can develop during treatment.^{82,99,111} Adverse drug reactions may prevent prolonged sulfonamide administration.¹³³ High doses of trimethoprim-sulfadiazine given for long periods to dogs and cats produces reversible myelosuppression (anemia and leukopenia).^{35,88} Drug susceptibility testing of *Nocardia* isolates is technically difficult and should be done at experienced laboratories. The National Committee for Clinical Laboratory Standards has approved a standard for susceptibility testing by broth microdilution,¹⁴³ and a comparative study of several conventional susceptibility testing methods has been published.⁴ PCR identification and drug susceptibility testing of *Nocardia* species can be done at the University of Texas Health Center at Tyler.*

AMK, Amikacin; A-C, amoxicillin-clavulanate;; AMP, ampicillin; CTX, cefotaxime; CTA, ceftriaxone; CIPRO, ciprofloxacin; ERY, erythromycin; IMP, imipenem; GENT, gentamicin; LNZ, linezolid; MINO, minocycline; T-S, trimethoprim-sulfamethoxazole; SULFA, sulfonamides; S, sensitive; I, intermediate sensitivity; R, resistant.

- a If data from only a small number of clinical isolates were available, the number of isolates is indicated in parentheses following the species name and susceptibility patterns are designated by S (sensitive), I (intermediate sensitivity) and R (resistant). When 2 letters (e.g., S/I) are present the first letter represents the susceptibility pattern of the majority of isolates.
- b To date, no clinical isolates have been tested.
- c *N. paucivorans* has tentatively been categorized as a type II *N. asteroides* complex based on a 99.7% 16S rRNA gene sequence similarity to *N. brevicatena*. (Yassin AF, et al. 2000. *Int J Sys Evol Microbiol* 50:803–809.)

Infectious Diseases of the Dog and Cat, 3rd Edition

- d Cited references report significantly different susceptibility patterns to third-generation cephalosporins.
- e Susceptibility data for *N. otitidiscaviarum* and *N. transvalensis* complex isolates are confounded by lack of separation of more recently identified species.
- f Approximately 50% of isolates were of only intermediate sensitivity.

460

461

Susceptibility studies have identified relatively characteristic species-associated resistance patterns (Table 49-4) and led to the use of various antibiotics other than or in conjunction with sulfonamides to treat nocardiosis in people. In vitro, combinations of imipenem with cefotaxime or trimethoprim-sulfamethoxazole and amikacin with trimethoprim-sulfamethoxazole were synergistic, increasing minimum inhibitory concentrations four times or more for the majority of 26 isolates of *N. asteroides* complex. Combinations of amikacin with imipenem or cefotaxime were predominantly additive.⁵³ Linezolid, an oxazolidinone, had in vitro activity against all *Nocardia* species tested.^{21,33,54} Based on in vitro data, topical imidazoles and ketoconazole may be effective against some *Nocardia* species.⁴¹ Treatment success has been reported with amikacin, ampicillin, broad-spectrum cephalosporin, clarithromycin, doxycycline, erythromycin, imipenem, minocycline, ofloxacin, and linezolid alone or in combination.^{82,99,83,104,130} Nocardiosis in animals that are severely ill, have systemic diseases, or have predisposing conditions may warrant initial combination drug therapy. If CNS disease is present, use of drugs with excellent CNS penetration, which include third-generation cephalosporins, imipenem, and linezolid, may be more effective than sulfonamides alone. Longer term use of linezolid in humans produces a reversible myelosuppression (anemia and thrombocytopenia)⁵⁰ and rarely has been associated with optic and peripheral neuropathies.^{79,80} Ideally, drug selection should be based on susceptibility studies of the isolate but if the information is not available, logical choices can be made using the in vitro data in Table 49-4. Substitution of antibiotics within a class of drugs may not provide effective treatment; for example, although sensitive to amikacin, *Nocardia farcinia* isolates are resistant to gentamicin (see Table 49-4), and although sensitive to minocycline, *N. brasiliensis* isolates are mostly resistant to doxycycline.⁵⁴ Drug susceptibility patterns of *Nocardia* species more recently isolated from human patients (*Nocardia abscessus*, *Nocardia asiatica*, *Nocardia cyriacigeorgici*, *Nocardia inohanensis*, *Nocardia yamanashiensis*, *Nocardia niigatensis*, and *Nocardia beijingensis*) have not yet been fully characterized.^{48,68-71}

In a review of 53 dogs with nocardiosis, 50% of the dogs died and 38.5% were euthanized.¹¹ Nine of 19 cats with nocardiosis either were euthanized or died.* The high mortality rate is partly attributable to predisposing conditions (distemper in dogs), delayed diagnosis, and inappropriate therapy. With earlier diagnosis and multidrug therapy, mortality of nocardiosis in animals may decrease to the rate reported in people. Only 19.8% of people with primary infections died, whereas 42.4% of patients with predisposing conditions and more than 50% of patients with either systemic or CNS nocardiosis died.¹⁰

49.2.7 Public Health Considerations

No cases of human nocardiosis acquired from direct contact with an infected dog or cat have been reported; however, several cases of cutaneous nocardiosis transmitted to people by a scratch or bite from clinically healthy cats and dogs have been documented.^{7,15,45,86,118} *Nocardia* species, which are ubiquitous in the soil,

Infectious Diseases of the Dog and Cat, 3rd Edition

can contaminate the claws and teeth of dogs and cats, although the risk of a person contracting nocardiosis by an animal bite or scratch wound is no greater than the risk associated with getting a puncture wound while gardening. Special precautions are warranted when a person with suppressed immunity (e.g., who is receiving immunosuppressive drug therapy, who has human immunodeficiency virus infection) is caring for a dog or cat with nocardiosis.

49.3 Acknowledgment

The author would like to thank Barbara Brown-Elliott, Mycobacteria/Nocardia Research Laboratory, Department of Microbiology, University of Texas Health Center at Tyler, for her comments regarding the methods used for speciation of *Nocardia* isolates.

50 CHAPTER 50 Mycobacterial Infections

Mycobacterial infections are caused by bacteria that belong to the family Mycobacteriaceae, order Actinomycetales. *Mycobacterium* is a genus comprising morphologically similar, aerobic, non-spore-forming, nonmotile bacteria with wide variations in host affinity and pathogenic potential. Historically, these bacteria have been subdivided into several groups and individual species, according to characteristic biochemical and cultural reactions (Table 50-1). Genetic sequencing studies have corroborated and extended this taxonomic classification. Molecular diagnostics have become more useful than phenotypic traits by classifying isolated mycobacteria according to their genetic relationships. Although cultural characteristics are less useful, growth rates and pigment formation continue to be a practical means of classifying these bacteria in the laboratory. This trait is because growth and biochemical characteristics often correlate with the virulence and form of disease produced in the mammalian host.

Mycobacteria have the distinctive property of retaining hot carbol-fuchsin and other stains after subsequent treatment with acid or alcohol, or both. The high lipid content of mycolic acid in the cell wall causes this acid-alcohol fastness. Cord factor and wax D, other surface constituents of mycobacterial cells, are partly responsible for the host's granulomatous response to the organism.

Mycobacteria are more resistant to heat, pH changes, and routine disinfection than are other pathogenic, non-spore-forming bacteria. Common disinfectants are often added to samples collected from nonsterile sites (e.g., sputum) for culture of mycobacteria to kill extraneous contaminating organisms. The minimum criteria established for pasteurization and heat disinfection were developed to kill mycobacteria. Mycobacteria are highly susceptible to dilute (5%) phenol or direct sunlight. Although they are relatively more stable in the presence of organic material, mycobacteria are killed by dilute (5%) household bleach within 15 minutes at room temperature.

On a clinical basis, mycobacteria are classified by their growth in culture—as being slow, difficult to cultivate, or rapid—whether they produce tubercles or granulomatous disease with or without dissemination. These features generally relate to the properties of the organisms that depend on their genetic relatedness. In this chapter, the organisms and diseases they cause will be divided into (1) slow-growing organisms that do or do not produce tubercles, (2) leproid granuloma-producing organisms, which cannot be cultured using standard methods, and (3) rapidly growing mycobacteria that are easy to cultivate. These organisms and the syndromes they cause will be discussed under the respective headings that follow.

50.1 INFECTIONS CAUSED BY SLOW-GROWING MYCOBACTERIA

Craig E. Greene

Danielle A. Gunn-Moore

50.1.1 Etiology

50.1.1.1 Tuberculous Mycobacteria

50.1.1.1.1 *Mycobacterium tuberculosis* and *Mycobacterium bovis*

These highly pathogenic tubercle-producing mycobacteria are facultative or obligate intracellular parasites. *M. tuberculosis* is the type species, and evidence of human disease dates back to the dawn of

Infectious Diseases of the Dog and Cat, 3rd Edition

civilization. *Tuberculous bacilli* (TB) are closely related species of mycobacteria that have been difficult to distinguish, except by using a few biochemical tests and nucleic acid probes. They possess mycolate-containing molecules in their cell walls, including the original cord factor trehalose 6,6'-dimycolate. These substances are associated with virulence and the production of characteristic tubercles (i.e., grossly small round translucent granulomatous lesions that histologically have central caseation surrounded by granulomatous inflammation). *M. bovis* is genetically and evolutionarily considered a subtype of *M. tuberculosis*. To be maintained in nature, they require infection of reservoir mammalian hosts because environmental survival is limited to a maximum of 1 to 2 weeks on infected fomites. The other members of the *M. tuberculosis* complex are *M. canettii*, a human pathogen; *M. microti*, a rodent pathogen that historically was reported to infect cats and has been found to infect people; *M. pinnipedii*, a seal bacillus; and *M. africanum*, a rare cause of human TB infections in Africa.

50.1.1.1.2 *Mycobacterium microti*—like

An unclassified variant with properties intermediate to *M. tuberculosis* and *M. bovis* (previously termed *M. tuberculosis*–*M. bovis* variant) has been identified as a common cause of TB infection in cats in Great Britain.^{20,70,71}

50.1.1.1.3 *Mycobacterium microti*

This organism of voles has been found in cats and was identified as a cause of infection in people using genetic analysis of mycobacterial isolates.^{148,186}

50.1.1.2 Nontuberculous Mycobacteria

50.1.1.2.1 *Mycobacterium avium* Complex

Other opportunistic, saprophytic mycobacteria that occur as granuloma-producing pathogens, which sometimes disseminate, are organisms related to and include *M. avium*. Considerable overlap occurs between the properties of *M. avium* and a closely related pathogen *M. intracellulare*. Because of this indistinct separation, *M. avium*–*M. intracellulare* or *M. avium* complex (MAC) has been used to refer to these organisms. In classification systems, they are labeled nontuberculous mycobacteria (NTM) or mycobacteria other than tuberculosis-complex organisms and produce granulomas but not true tubercles. Their slow growth during cultivation makes them similar to tuberculous bacteria. In adult humans, MAC organisms produce pulmonary infiltrates and disseminated disease, generally in immunocompromised hosts. In cats and children, localized lymphadenitis can occur. When newer methods of genetic analysis have been performed, some cases clinically classified as feline leprosy syndrome (see next section) have been attributed to MAC infection. Although in cats, MAC disease often becomes disseminated, in dogs, granuloma formation often occurs in visceral organs with only occasional dissemination to other tissues. As an opportunistic disease, MAC infection is more likely in immunocompromised hosts.⁶⁶ Among opportunistic mycobacteria in people and animals, MAC organisms are the most likely to produce bacteremia and multiple-organ disseminated disease.

FI, Facultative intracellular; OI, obligate intracellular; S, saprophyte; ?, uncertain.

a Older (Runyon's) classification system for atypical mycobacteria bases on cultural properties: I photochromogens: produce yellow pigment on exposure to light, buff color on growth in dark. II scotochromogens: produce orange pigment, independent of light. III nonchromogens: filamentous forms, buff or yellow regardless of amount of light; slow growth (nonphotochromogens). IV nonchromogens: rapid growth, mature colonies in 4 to 6 days at 37° C, most others require 1 to 2 weeks.

b Included in tuberculous group in this chapter because produces clinically similar disease. Growth enhanced by glycerol and 42° C.

c Because of taxonomic uncertainties, organisms of *M. chelonae* and *M. abscessus* are hyphenated.

Infectious Diseases of the Dog and Cat, 3rd Edition

Serotyping by agglutination reactions has been classically used to differentiate MAC isolates. However, now, nucleic acid probes are used for their rapid identification. Using serologic methods, MAC organisms consist of 28 serovars; 1 through 6 and 8 through 11 are assigned to *M. avium*, and 7, 12 through 17, 19, 20, and 25 are assigned to *M. intracellulare*.^{89,181} Serotypes 1 and 4 have been isolated from cats, and serotypes 1, 2, and 4 have been isolated from dogs.⁹⁶ Currently, MAC organisms are distinguished by nucleic acid profiles (see Organism Detection later in this chapter).

50.1.1.2.2 Other Slow-Growing Saprophytic Mycobacteria

M. kansasii, *M. genavense*, *M. simiae*, and the *M. terrae* group (including *M. terrae*, *M. nonchromogenicum*, and *M. triviale*) are all slow-growing saprobes that have cultural characteristics in common with the MAC organisms. In dogs and cats, they generally produce disease similar to MAC organisms, characterized by localized pyogranulomatous lesions, usually in the lungs with complicating pyothorax or as a cause of widely disseminated disease. Although classified in this group, the *M. terrae*-group organisms often cause cutaneous lesions similar to the rapid-growing organisms (see later discussion).

50.1.2 Epidemiology

50.1.2.1 Tuberculous Mycobacteria

50.1.2.1.1 *M. tuberculosis*

Human beings are the only reservoir hosts for *M. tuberculosis*. Dogs and cats are susceptible to infections by *M. tuberculosis* and *M. bovis*. Cats are naturally much more resistant to *M. tuberculosis* than they are to *M. bovis*, while both dogs and cats are more resistant than people are to infection by MAC organisms. Despite this inherent resistance, exposure to MAC organisms is much greater because they are ubiquitous in the environment. Canine and feline infections with *M. tuberculosis* are considered an anthroponosis; the direction of transmission is from people to animal (Fig. 50-1). Although pets acquire the infection from people, the spread back from dogs or cats to people has not been reported. Dogs have had a higher prevalence of infection with *M. tuberculosis* than have cats. Dogs with tuberculous pneumonitis discharge organisms in the sputum as do infected people. Aerosolized droplets are the primary means of transmission of this disease. Airborne droplet nuclei from respiratory secretions fall to the ground where they temporarily remain viable but stationary and thus relatively noninfectious for other people and pets. Only small (3 to 5 μ m) diameter particles can successfully bypass upper respiratory clearance mechanisms and deposit in alveoli. Discharges that are not airborne may potentially be infectious to dogs and cats exposed through close contact. In general, tubercle bacilli are not as transmittable as other bacterial pathogens because prolonged, frequent exposure or large inocula are usually required. Because of measures imposed to control infection in people, the overall prevalence of human and animal *M. tuberculosis* infections had been decreasing in developed countries. Relative increases have occurred in densely populated urban areas and in economically depressed areas. The interrelated factors of homelessness, illicit drug use, and human immunodeficiency virus (HIV) infection have caused unanticipated increases in its prevalence. Multiple-drug-resistant tuberculosis has emerged in these so-affected populations because of irregular compliance with drug therapy. Pets in such environments will have an increased risk of becoming infected. The incidence of *M. tuberculosis* infections in the United States is highest in Atlantic coast metropolitan regions and in the southeastern regions.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 50-1 Epidemiology of tuberculosis in the dog and cat. Width and direction of arrows indicate the relative frequency and usual sources of infection. (Courtesy University of Georgia, Athens, Ga.)

M. tuberculosis infection has become an important emerging anthroponozoonosis in free-ranging wildlife. Until recently, the infection was identified only in wildlife or captive zoo animals such as elephants that had close and prolonged contact with people.^{135,143} Infections caused by *M. tuberculosis* have been increasing in recent years, especially in underdeveloped countries, as a result of the acquired immunodeficiency syndrome (AIDS) epidemic. In Africa, expansion of ecotourism and changing land use have increased contact between infected people and free-living animals. Wild animals living in close proximity to human habitations and refuse sites have become infected. Certain wildlife populations have become endemically infected, such as the banded mongoose (*Mungos mungo*) in Botswana and suricates (*Suricata suricatta*) in South Africa.³

50.1.2.1.2

Mycobacterium bovis

This organism has a wide host range, including many animals and people, and a worldwide geographic distribution.⁷² In most industrialized countries, bovine tuberculosis has been controlled with surveillance, testing and slaughter, and pasteurization of dairy products. In developing countries, tuberculosis caused by

Infectious Diseases of the Dog and Cat, 3rd Edition

M. bovis has become widespread and a potential risk for exposed people and animals.⁴¹ With respect to *M. bovis* infections, the gastrointestinal (GI) tract is the most common portal of entry. Cats and dogs can be potential disseminators of disease when the organism preferentially localizes in the intestinal or respiratory tracts. Because of localization of infection, cats usually excrete the organism via feces and dogs via sputum. *M. bovis* does not endure long in the environment, and reservoir hosts are essential for survival of the organism. Outside its hosts, the organism survives for a period varying from 4 days in summer to less than 28 days in winter.⁹² Organisms may persist for several months in organic material such as feces or carcasses.^{166,178} Dogs and cats acquire infection when they consume contaminated milk or scavenge contaminated carcasses. Dogs and cats may be involved in the maintenance of bovine tuberculosis on farms, where it is enzootic, and may be rarely responsible for transmission of the bovine bacillus to people (see Fig. 50-1). Subclinically, infected dogs and cats sometimes remain on farms after reactor cattle have been identified and removed from the herd, and farms or families with recurrent TB infections should have their pet animal contacts checked periodically. Rarely, spread of *M. bovis* between people has been reported.

Cats are more commonly infected with the bovine bacillus than dogs are; and on an experimental basis, cats appear to be more susceptible to bovine than to human TB. Part of this affinity is related to the frequent ingestion of contaminated, unpasteurized milk or uncooked meat or offal from infected cattle. Milk is an ideal medium for the organism because it buffers the gastric acid that normally prevents colonization of the lower GI tract with TB. Dogs and cats may also acquire TB from uncooked, infected meat used as cat and dog foods. As a result of eradication measures, the prevalence of bovine tuberculosis is low in the United States. Increased use of commercial foods and trends to urban living have reduced the prevalence of bovine tuberculosis in dogs and cats.

Despite the reduction of infection in domestic animals, bovine TB remains a problem worldwide, except in Australia, because it has become established in wildlife hosts that have acquired infection from cattle and that act as continued reservoirs for infection. As a result, domestic animals such as cattle, cats, and dogs continue to become infected.^{46,47,159,185} For example, in Great Britain and Ireland, badgers (*Meles meles*) and foxes (*Vulpes vulpes*) have become a major wildlife reservoir.⁴⁴ Although transmission between badgers is predominantly by aerosols, *M. bovis* has also been found in their bite wounds suggesting cutaneous inoculation. Following a cattle outbreak in Cornwall, infection in domestic cats on the farm and local badgers all shared the same spoligotype.¹⁴¹ Interestingly, no cattle had been recently kept on the premises suggesting that local badgers had somehow infected the resident cat population. In New Zealand, feral brushtail possums (*Trichosurus vulpecula*) and deer act as reservoir hosts; wild ferrets, pigs, cats, and goats are amplifier hosts whose carcasses infect carrion-eating animals. Amplifier hosts can become infected from carnivorous ingestion. Sheep, horses, and hedgehogs are spillover hosts that are incidentally infected.⁴⁰ Stoats, dogs, hares, rabbits, and many small rodents, are occasional dead-end hosts.

Captive and free-living exotic wildlife carnivores, including nondomestic canids and felids, and domestic and feral dogs and cats have been most commonly infected with *M. bovis*. Ingestion of infected carrion is the most common source of infection. The infection is maintained in gregarious herbivores, while carnivorous predators such as lions (*Panthera leo*), cheetahs (*Acinonyx jubatus*), leopards (*P. pardus*), spotted hyenas (*Crocuta crocuta*), Iberian lynx (*Lynx pardina*), Siberian tiger (*P. tigris longipilis*), snow leopard (*Uncia uncia*), and feral domestic cats have become secondarily infected.* Additional subsequent transmission of infection via aerosol or biting between gregarious carnivores, such as lions, has been suspected.¹⁰³

Infectious Diseases of the Dog and Cat, 3rd Edition

* References: 14, 25, 103, 112, 121, 180.

50.1.2.1.3

M. microti-like

Identified in Great Britain, the variant species was found predominantly in rural cats with avid hunting behavior. The source of infection is believed to be a prey species. Some previous reports of this infection from the United Kingdom may have been mistaken for *M. bovis* infections.²⁰ Currently, the relationship of this variant to *M. microti* is uncertain, but it is likely that they are very closely related.

50.1.2.1.4

M. microti

Infection with *M. microti* has been described in cats.⁸⁵ Infection from rodents is considered the source of infection for cats and people. Pulmonary infection was found in the people who had no underlying evidence of immunodeficiency.

50.1.2.2

Nontuberculous Mycobacteria

50.1.2.2.1

M. avium Complex

These organisms are ubiquitous worldwide in soil and water under certain conditions. MAC organisms have been shown to be present in acidic (pH 5.0 to 5.5) conditions and soils high in organic matter.¹⁰⁷ These conditions are met in acidic swamp areas, coastal plains, and brackish coastal waters. Feces of infected birds contain large numbers of bacilli, and infection of dogs and cats occurs from ingestion of infected meat or contact with infected soil or with fomites contaminated by poultry carcasses or feces (see Fig. 50-1). Unlike *M. tuberculosis* and *M. bovis*, MAC organisms remain viable for at least 2 years in the environment, including municipal water supplies, soil, dairy products, and tissues of birds and mammals. Natural, potable, and even treated water supplies in temperate and tropical regions can harbor nontuberculous mycobacteria. These organisms can exist within biofilms that coat the internal surfaces of water pipes, fixtures, and storage tanks. MAC organisms are likely to be found in recirculating water systems commonly used in human hospitals.¹⁵⁴ Hot water has a higher degree of colonization and chlorine does not inactivate these organisms, especially at higher temperatures. In hospital environments, bathing, rinse, lavage, and disinfectant solutions made with potable water can become contaminated with MAC and NTM organisms. Endoscopy equipment can be similarly infected during cleaning.

465

466

Despite the widespread nature of MAC organisms, infections in dogs and cats have been rare owing to their innate resistance. Poultry and swine are primarily susceptible to MAC infection after contact with infected food or water.

The importance of infection with MAC organisms is that they produce granulomas of deeper tissue and parenchymal organs that are grossly indistinguishable from those caused by mammalian tubercle bacilli. No evidence has been found for spread of MAC organisms between or within animals and people.

50.1.2.2.2

Other Slow-Growing Saprophytic Mycobacteria

The natural habitat of organisms such as *M. kansasii*, *M. simiae*, *M. terrae*, and *M. genavense* is likely the environment. They can be isolated from the sputum and stool of clinically healthy people and animals

Infectious Diseases of the Dog and Cat, 3rd Edition

indicating exposure and contamination or colonization without establishment of clinical infection. The pathogenicity of these organisms is thought to be low, and they cause disease mainly in immunocompromised hosts.

50.1.3 Pathogenesis

Tubercle bacilli enter the body through either the respiratory or alimentary tract or skin penetration, depending on the initial route of exposure. Local multiplication of the bacillus may develop at the initial site of deposition—termed a primary complex—as well as in the regional draining lymph node. Granuloma formation occurs at both sites. Incomplete primary complex refers to infection and localization in the lymph node without lesion formation at the site of deposition. Cats more commonly form incomplete primary complexes whether tonsils, mandibular lymph nodes, or ileocecal lymph nodes are infected; the last are the most common sites for localization and shedding of *M. bovis* organisms. Dogs, which more commonly acquire *M. tuberculosis*, tend to develop respiratory infections with complete primary complex formation and lesions both in the lungs and hilar lymph nodes. *M. tuberculosis* more readily infects the respiratory tract because of its high oxygen requirements. Infections involving MAC organisms in dogs and cats have often been disseminated throughout lymphoid and many other tissues, without indications of a primary granuloma at the site of entry.

The cytokine staining pattern of feline mucocutaneous mycobacteriosis is similar to that described for human leprosy in which T cell–mediated response leads to epithelioid granulomas with abundant CD4⁺ type 1 helper T (Th1) cells and upregulation of the cytokines interleukin (IL)-1b, tumor necrosis factor (TNF)-α, IL-6, and granulocyte-macrophage colony-stimulating factor.¹⁰⁶

Not all initial exposures to mycobacteria result in the formation of persistent granulomas because in most individuals, immune responses usually limit further multiplication and spread of the agent. The initial inflammatory response may then subside and resolve, with healing and fibrosis if the remaining tubercle bacilli can be eliminated. The production of persistent focal or disseminated disease is suggestive of defective cell-mediated immunity (CMI). With decreased immunologic resistance, the mycobacteria merely become confined within phagocytic cells where they continue to multiply because of the body's inefficiency in eliminating these intracellular pathogens. Granuloma formation is therefore a reflection of the body's attempt to contain remaining organisms. These viable organisms may remain dormant only to break out later and spread as a result of immunosuppression.

In a certain percentage of animals, the mycobacteria appear to outpace the host defense mechanism, resulting in progressive disease. This increased virulence may result from alterations in the route of exposure, size of inoculum, strain pathogenicity, and CMI defense mechanisms. Having produced primary lesions, the tuberculous mycobacteria may disseminate throughout the body, spreading the infection into adjacent tissue by direct extension or by mechanical means. Aspiration and gravitation of infectious exudates may spread the disease through other areas of lung tissue. Intracellular multiplication of the bacteria is unimpeded as the infection spreads to other tissues by lymphatic or hematogenous means.

A higher prevalence of *M. tuberculosis* infection has been observed in people with AIDS. In contrast, no clear association has been made between feline retroviral infection and mycobacteriosis. Certain breeds, such as the basset hound, the miniature schnauzer, Siamese cat, and Abyssinian cat, are over-represented in reports of MAC infection. Siamese cats are similarly predisposed to infections with other persistent intracellular organisms. Although likely, the precise defects in the immune system of these breeds have not been determined.

Infectious Diseases of the Dog and Cat, 3rd Edition

The factors that contribute to mycobacterial resistance by the host are unclear.⁹¹ CMI is typically associated with protection against facultative intracellular pathogens such as mycobacteria. Increased resistance seems to be associated with the enhanced capacity of activated macrophages to kill tubercle bacilli or to inhibit their intracellular multiplication. In people with refractory pulmonary mycobacteriosis caused by non-*M. tuberculosis* organisms, a defect in interferon (IFN)- γ secretion has been documented.¹⁶⁵

Infection with MAC organisms usually begins with ingestion of the organism from the environment or contaminated food or infected uncooked viscera. These organisms are closely related to *M. avium* subspecies paratuberculosis, the cause of Johne's disease, which is chronic granulomatous enteritis of ruminants and other herbivores. With Johne's disease, animals may acquire infection as neonates, through eating contaminated food or exposure to a contaminated environment. The mycobacteria may be phagocytized by intestinal macrophages at which time the infection becomes quiescent. Eventually, with stress or acquired or inborn immunosuppression, the organisms replicate and the disease occurs. Similar events are suspected to occur in MAC infections of dog breeds, such as the basset and miniature schnauzer, which develop illness within the first few years of life, likely as the result of unrecognized defects in CMI. In some animals with severe immunosuppression, bacteremia may result and multiple organ dissemination ensues.

50.1.4 Clinical Findings

Table 50-2 reviews the clinical features of disease caused by the various mycobacterial species.

50.1.4.1 Tuberculous Mycobacteria

50.1.4.1.1 *M. tuberculosis* and *M. bovis*

Canine and feline tuberculosis is frequently a subclinical disease. Many pets become inadvertently infected with *M. tuberculosis* while living in the same household with tuberculous owners. Farm pets also may serve as subclinical reservoirs of *M. bovis* for susceptible cattle.

When clinical signs occur in dogs and cats, they reflect the site of granuloma formation. *M. tuberculosis* is more likely to cause pulmonary infections than is *M. bovis*, which often affects the GI tract. With respiratory involvement, bronchopneumonia, pulmonary nodule formation, and hilar lymphadenomegaly are most common in dogs, causing fever, weight loss, anorexia, and harsh nonproductive coughing.⁶¹

Dogs and cats may develop dysphagia, retching, hypersalivation, and tonsillar enlargement, all the result of ulcerated and chronically draining oropharyngeal lesions. Cats develop primary intestinal localization more commonly than dogs, and they exhibit weight loss, anemia, vomiting, and diarrhea as signs of intestinal malabsorption. Mesenteric lymph nodes are palpably enlarged. Abdominal effusion is present in some cases.

ORGANISM	ENVIRONMENTAL FACTORS	CLINICAL FEATURES	DRUG SUSCEPTIBILITY OR REPORTED SUCCESSFUL THERAPY ^a
Slow-Growing Tuberculous: Tubercles and Lymphadenitis, Occasional Dissemination			
<i>M. tuberculosis</i>	Urban, close contact affected person	Usually respiratory, pulmonary localization, can disseminate systemically	Isoniazid, rifampin, ethambutol, pyrazinamide
<i>M. bovis</i>	Rural cats, ingest raw beef or dairy products	Usually alimentary disorders, may get respiratory, cutaneous or lymphatic involvement, sometimes systemic dissemination	Rifampin, clarithromycin, fluoroquinolones, ethambutol, isoniazid, surgical excision of skin lesions
<i>M. microti</i> —like	Rural, suburban, hunter, bite wounds, prey exposure	Nodular cutaneous lesions draining, ulceration, peripheral lymphadenomegaly, local myositis, arthritis, osteomyelitis, sometimes systemic dissemination	Clarithromycin, fluoroquinolones, rifampin
Lepromatous: Cutaneous Nodular Dermatitis			
<i>M. lepraemurium</i>	Cooler wet climates, winter months, cats under 3 yrs of age exposed to infected rodent prey	Single to multiple cutaneous and subcutaneous dermal nodules on head and extremities, ulcers, fistulas, abscesses regional spread only	Clofazamine, clarithromycin, doxycycline or minocycline, rifampin, surgical removal
Feline leprosy, novel species	Central coast New South Wales, Australia, New Zealand, older cats over 10 yrs of age, feline immunodeficiency virus predisposes	Multiple subcutaneous dermal nodules, no ulceration, sometimes dissemination	Clarithromycin, rifampin, clofazimine
Candidatus <i>M. visibilis</i>	Environmental exposure	Cutaneous and disseminated	Clofazamine
Nontuberculous: Pyogranulomatous			
Saprophytic Slow Growing: Cutaneous Lesions, Lymphadenitis, Dissemination in Immunocompromised Hosts			
<i>M. avium</i> —complex	Exposure to infected soil, water or dust; acidic soils contaminated with bird feces or carcasses, Bassett hounds and Siamese cats most prevalence	Dermal and regional lymph node granulomas, alimentary infiltration, corneal granulomas, systemic dissemination	Clarithromycin, clofazimine, doxycycline or minocycline, rifabutin, ethambutol; rifampin preferred if central nervous system involvement for better penetration
<i>M. genavense</i>	Environmental exposure in immunocompromised host	Disseminated lymphadenitis	Clarithromycin, ethambutol, fluoroquinolones, clofazimine
<i>M. terrae</i> complex	Environmental exposure	Cutaneous lesions	Clarithromycin, fluoroquinolones, rifampin
<i>M. simiae</i>	Environmental exposure	Cutaneous and disseminated	Clarithromycin, fluoroquinolones, rifampin?

Infectious Diseases of the Dog and Cat, 3rd Edition

Canine leproid granuloma, novel species	Probably worldwide, biting flies	Subcutaneous nodules especially on the head and ears	Surgical removal, rifampin, clarithromycin
Saprophytic Fast Growing: Cutaneous and Subcutaneous Pyogranulomatous Infections			
<i>M. thermoresistibile</i>	Soil and house dust, inhaled water, wound contaminant	Pyogranulomatous pneumonia, pyothorax, cutaneous and subcutaneous pyogranulomas	Doxycycline, clarithromycin
Other fast-growing opportunistic and species	Soil and water exposure; bite and puncture wounds; immunocompromised host	Cutaneous and subcutaneous granulomas, especially inguinal region, ulcers, drainage, with regional spread only Secondary wound infections	Surgical removal, wide excision, variable susceptibility to fluoroquinolones, doxycycline, aminoglycosides, clofazimine, clarithromycin, trimethoprim-sulfonamide

- a For dosages and detailed information on each, see [Tables 50-4 to 50-7](#) and [50-9](#) and Drug Formulary, [Appendix 8](#). A minimum of two and often three drugs should always be used in combination.

A continuum of clinical signs develops with disseminated disease. Direct extension of lung disease can result in pleural or pericardial effusion with signs of dyspnea, cyanosis, and right-sided heart failure. Dissemination from the GI tract to other tissues including the lungs has been commonly reported with longstanding infections in lions and cheetahs.^{102,103} Dissemination from cutaneous lesions to the lungs has been observed in cats with *M. bovis* infections and can cause respiratory dysfunction. Disseminated disease may be the first sign of illness in many dogs and cats, and clinical signs are correlated with the organ localization in each case. Generalized lymphadenomegaly, anorexia, weight loss, fever, and sudden death may be observed. Masses or enlargement may be detected in many abdominal organs, especially the liver and spleen. Dermal nodules and nonhealing, draining ulcers have been noted commonly in cats and sometimes in dogs. Cats with *M. bovis* infections have developed tuberculous choroiditis and retinal detachments.⁵⁶ Granulomatous uveitis and central nervous system (CNS) signs have occurred in some cases. Lameness and spontaneous fractures have been observed with bone localization. Additional clinical signs have included hemoptysis, hematuria, and icterus.

50.1.4.1.2 *M. microti*-like

Cats with these infections usually develop cutaneous granulomas at the site of a bite or scratch wound or other penetrating injury ([Figs. 50-2, A and B](#)). Lesions often develop drainage and associated regional lymphadenomegaly. Organisms may disseminate subsequently causing infection of multiple organs.

50.1.4.2 Nontuberculous Mycobacteria

50.1.4.2.1 *Mycobacterium avium* Complex

The ubiquitous distribution of MAC organisms in the environment compared with the low prevalence of the disease also suggests that subclinical infections are common. Dogs with MAC-induced disease have usually had extensive granulomatous disease of the bowel, spleen, liver, and mesenteric lymph nodes. Most dogs have been less than 4 years of age, and it is evident from lesions that the disease has been

Infectious Diseases of the Dog and Cat, 3rd Edition

subclinical and progressive. Weight loss and lethargy are predominating clinical signs. Vomiting, anorexia, fever, diarrhea, and hematochezia have been observed, but these may be intermittent. Other signs in some dogs have been paraspinal hyperesthesia, paresis, lameness, subcutaneous swellings, anterior uveitis, and respiratory difficulty.⁷⁸

Cats with MAC infections often have developed enlargement of regional lymph nodes and subcutaneous swellings, especially around the head and face, and in some cases keratitis (Fig. 50-3).^{*} These infections often follow bite or scratch wounds to the face. Weight loss, anorexia, and fever have been observed.

Dissemination can occur to many tissues in some cats, and the clinical signs reflect the area involved.¹²

Cats can develop visceral disease similar to dogs where thickened intestinal loops, hepatomegaly, splenomegaly, and intestinal lymph node enlargement can be palpated or observed (Fig. 50-4).

Dissemination from GI viscera can produce respiratory dysfunction from pulmonary nodular interstitial infiltration.

Being environmentally resistant and an opportunist, *M. avium* infection has been implicated in outbreaks of hypersensitivity or granulomatous pneumonitis in people.⁵³ Aerosolized droplets of disinfected (e.g., chlorinated) water has been responsible for inflammatory reactions in the lungs of people and might also occur in their animals.

* References: 48, 101, 123, 139, 174.

50.1.4.2.2

Other Slow-Growing Saprophytic Mycobacteria

M. genavense, a fastidious MAC-like organism, is the cause of muscle wasting, small-bowel wall thickening, and hepatic granulomatous infiltration in birds and in humans with AIDS.²³ Pulmonary and disseminated infection with *M. genavense* has been found in dogs and an immunodeficiency virus (FIV)-infected cat.^{82,104} *M. kansasii* caused pneumonia with pulmonary abscess formation and pyothorax in a dog.¹⁵⁸ *M. terrae* complex caused nodular dermal thickening of a digit of a cat.⁷⁴ Disseminated disease associated with multiple cutaneous nodules and ocular (chorioretinitis) and pulmonary involvement was found in a cat with *M. simiae* infection.⁴⁹

50.1.5

Diagnosis

50.1.5.1

Clinical Laboratory Findings

Clinical laboratory findings in mycobacterial infections are frequently nonspecific and include moderate leukocytosis and anemia. The anemia is usually nonregenerative, but in some cats with intestinal infections, is reportedly macrocytic.⁹⁶ Normal to reduced serum albumin levels and hyperglobulinemia are frequently apparent. Hypercalcemia may be present as a result of the granulomatous inflammation as observed in other mycobacterial infections.^{1,133} Organisms may be visualized in leukocytes of blood and bone marrow smears or buffy coat preparations or urine.^{38,183} The lipid-containing cell wall does not stain with Romanovsky's stains so that bacilli appear as unstained bars within leukocytes.

Fig 50-3 Mass lesion in the upper palate and maxillary region of a cat from localized *M. avium*-intracellulare infection. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

With MAC infection, dogs have had anemia, leukocytosis, lymphopenia, hypoalbuminemia, and increased liver enzyme activities. Hilar lymphadenomegaly is often visible with thoracic radiography. In one dog, organisms were observed with acid-fast stained fecal smears.⁷⁸ Cats typically have anemia, neutrophilic leukocytosis, and hyperglobulinemia.

Fig 50-4 Intestinal mesenteric granulomas examined by exploratory laparotomy of a cat with disseminated *M. avium*–intracellular infection. (Courtesy B. Flatland, University of Georgia, Athens, Ga.)

Radiographically and ultrasonographically visible masses may be apparent in various organ systems. Abnormalities on thoracic radiography can include tracheobronchial lymphadenomegaly and interstitial pulmonary infiltrates; calcified pulmonary lesions may be observed (Fig. 50-5). Lung consolidation and granuloma formation have been associated with diffuse radiopaque densities in lung lobes. Metastatic lesions from dissemination are seen as diffuse miliary densities (Figs. 50-6, A and B). Fluid may be present in the pleural or pericardial cavities. Abdominal radiography may reveal enlargement of parenchymal organs such as the liver and spleen or solitary abdominal masses. Fluid may be present in the abdominal cavity, and calcified mesenteric lymph nodes may be evident. Bony lesions consist of small, circumscribed, radiolucent areas. Thoracic involvement may be associated with hypertrophic pulmonary osteopathy. Diskospondylitis or vertebral osteomyelitis may be apparent.

469

470

Note the multiple irregular mineralization of soft tissue in the craniodorsal thorax and cranial abdomen. (From Lui S, Weitzman L, Johnson GG. 1980. Canine tuberculosis, *J Am Vet Med Assoc* 177:164–167. Reprinted with permission.)

50.1.5.2 Cytology

Specimens should be obtained from tissue aspirates or impression smears taken by biopsy or at necropsy. The acid-fast stain is the most widely available method for making a rapid presumptive diagnosis of mycobacterial infection. Acid-fast stains will be positive for specimens from many but not all animals with mycobacterial infections. It is more consistent for organisms recovered in culture. Mycobacteria can be stained for acid fastness with carbol-fuchsin or fluorescent dyes (i.e., auramine-rhodamine). The fluorochrome stains are more sensitive and technically less difficult to examine than conventional carbol-fuchsin stains. For enteric infections with organisms such as *M. avium* or *M. bovis*, acid-fast staining of rectal scrapings or fecal mucus may detect organisms.

50.1.5.3 Tuberculin Testing

Tuberculin is a purified protein derivative (PPD) from *M. tuberculosis*. People or animals infected with tubercle-producing mycobacteria develop a delayed hypersensitivity reaction when this antigen is injected intradermally (ID). Nontuberculosis mycobacteria contain proteins analogous to *M. tuberculosis*, and considerable cross-reactivity exists. ID skin testing has been used as an aid in the detection and diagnosis of

Infectious Diseases of the Dog and Cat, 3rd Edition

human tuberculosis and to evaluate delayed-type hypersensitivity in animals. The two types of tuberculin used for ID testing are summarized in [Table 50-3](#). Depending on whether a history of infection or disease exists, various strengths (1, 5, or 250 tuberculin units/0.1 ml) of PPD are usually selected in human skin testing. However, the highest concentration is needed to test dogs. ID tuberculin testing in dogs is reportedly inconsistent and unreliable. In contrast, use of the pinna showed reliability in detecting dogs previously sensitized with bacille Calmette-Guérin (BCG) vaccine, an attenuated mutant strain of *M. bovis* that has been used in people as a vaccine to induce resistance to tuberculosis and as a nonspecific immunostimulant. In addition, infected dogs have been shown to respond well to ID skin testing with BCG. A disadvantage of BCG is that it can induce later false-positive reactions in skin testing with PPD. Although not studied in animals, false-positive results have been more common in people using certain brands of PPD.¹⁶⁴ BCG must be handled cautiously to avoid inadvertent inoculation because immunosuppressed people, especially those with AIDS, or immunocompromised animals being tested may develop disseminated disease.^{177,188,189} Both tuberculous and nontuberculous mycobacterial infections give positive results with ID tuberculin or BCG testing.

Tests are performed by injecting BCG or PPD ID on the medial side of the proximal hind limb or, preferably, on the inner surface of the pinna. A positive reaction is indicated only if a raised, indurated, and subsequently necrotic swelling appears at the site of injection between 48 and 72 hours later. Necrosis and ulceration may take up to 2 weeks to develop. Mild erythema after ID BCG injection in dogs is considered nonspecific. False-positive results caused by cross-reactivity with other bacterial species have been observed.

Another method of tuberculin testing for dogs, recommended by the U.S. Department of Agriculture (USDA), requires that a baseline rectal temperature be taken. If it is in the reference range, inject Subcutaneous (SC) 0.75 ml PPD bovis (as supplied by USDA, see [Table 50-3](#)). The rectal temperature is monitored every 2 hours for 12 hours. A 1.1° C (2° F) rise in temperature is interpreted as a positive test result.

Unlike many species, cats do not react strongly to ID-administered tuberculin. Despite their lack of response to PPD, cats still have adequate immunity to tuberculosis. SC or intravenous (IV) challenge with tuberculin is no more reliable, and cats do not respond well to ID BCG. Cats sensitized to BCG have responded to PPD injected ID in the pinna; unfortunately, the response has usually been inconsistent, infrequent, or transient. The SC method has not been evaluated in cats, and biopsy, culture, and necropsy are more definitive tests. Tuberculin testing has been effectively used in lions by inoculating ID in the cervical region.¹⁰³

50.1.5.4

Serologic Testing

Although unreliable compared with skin testing, serologic testing for antimycobacterial antibodies includes hemagglutination and complement fixation. Serologic testing has been employed to detect infected dogs and cats when skin testing was inconclusive. The serologic response to *M. bovis* BCG vaccination in cats and dogs has been evaluated with immunoblotting against specific protein antigens.²¹ Antibody increases were detected 3 to 5 weeks after vaccination and remained increased for 23 weeks and longer than 1 year in dogs and cats, respectively. Serologic testing may potentially detect exposure to mycobacteria similar to ID skin testing. Unfortunately, antibodies to mycobacteria such as BCG react with a wide variety of bacteria, fungi, and protozoa. This feature has been employed as a histochemical procedure to detect microorganisms in tissues.²²

Infectious Diseases of the Dog and Cat, 3rd Edition

50.1.5.5 Bacterial Isolation

Mycobacterial culture is the reference standard for diagnosis. In collection of specimens for *M. tuberculosis*, direct inoculation of pleural exudates into media gives a greater yield than that following transport of the specimen to the laboratory.³⁵ Addition of heparin to the specimen gave similar results to direct inoculation, presumably because the organisms trapped in coagulated material could not be cultured. For culture, tissue- or mucosa-derived samples are usually treated with 4% sodium hydroxide and another disinfectant such as N-acetyl-L-cysteine to eliminate any contaminating microorganisms. Specimens that are usually sterile (internal tissues, cerebral spinal fluid, urine, blood) should not be decontaminated because the viability of low numbers of mycobacteria present can be lost. When specimens are small and contain acid-fast organisms, the entire sample should be placed in a broth-based culture medium. Broth or liquid media facilitate more rapid growth and higher yields of mycobacteria. Solid media are still required for optimal isolation of mycobacteria and for detection of more than one species in a specimen. Pathogenic tuberculous mycobacteria are slow-growing, often requiring 4 to 6 weeks to establish visible colonies on solid media, and their growth is inhibited unless enrichment media are used. Egg-enrichment media such as Lowenstein-Jensen (LJ) and agar-based media such as Middlebrook (both from Difco Labs, Detroit, Mich.) are preferred as solid media for isolating tubercle bacilli. Glycerol, which is added to media such as LJ to enhance the growth of *M. tuberculosis*, actually inhibits the growth of *M. bovis*. Stonebrink's or B83 media are used when *M. bovis* is suspected.⁴² Growth is more rapid in 5% to 10% carbon dioxide. Some saprophytic species such as *M. genavense* grow better under microaerophilic conditions of reduced (2.5%) oxygen tension.¹⁶¹ Pathogenic and saprophytic mycobacteria have been identified and differentiated by colony growth and biochemical characteristics (see Table 50-1).

Table 50-3 Summary of Intradermal Skin Testing for Tuberculosis in Dogs and Cats^a

SUBSTANCE	PREFERRED SITE	DOSE
PPD	Inner surface pinna	250 TU ^b (0.1 ml)
BCG	Inner surface pinna	0.1–0.2 ml ^c
BCG, Bacilli Calmette-Guérin; PPD, purified protein derivative of tuberculin; TU, tuberculin units.		

- a See text for information on performance and interpretation of the test.
- b PPD for bovine testing from U.S. Department of Agriculture is 30,000 TU/ml (1 mg/ml). To prepare at least 250 TU/0.1 ml, remove 0.1 ml as supplied; add to 1.1 ml sterile water for injection; mix in sterile glass vial. Diluted solutions of PPD should be made fresh and used soon after preparation. Human (*M. tuberculosis*) or bovine (*M. bovis*) strains can be used for tuberculin source because cross-reactions exist to cell wall components. The human strain might give a stronger reaction to *M. tuberculosis* but bovine is available in higher concentration. Higher concentrations are used to test animals than people when sensitivity rather than specificity is more important when public health risk exists. NOTE: in people, 5 TU units in 0.1 ml of solution (50 TU/ml) are used on volar aspect forearm and read in 48–72 hours. If human tuberculin is supplied in milligrams, the conversion factor is 50,000 U of PPD equals 1 mg of PPD.
- c BCG vaccine USP contains 8–26 million colony-forming units/ml of living bacillus. Reconstitute freeze-dried preparation into 1-ml aliquots according to manufacturer's recommendation. BCG may sensitize the animal to false-positive results to further tuberculin testing.

Infectious Diseases of the Dog and Cat, 3rd Edition

Commercial methods have been developed that facilitate rapid detection and classification of the mycobacteria. The lysis-centrifugation method (Isolator system, Wampole Labs, Cranbury, N.J.) has also been used to facilitate culture of intracellular pathogens such as mycobacteria from blood. Radiometric automated methods for broth culture such as the BACTEC system (Becton Dickinson Microbiology Systems, Sparks, Md.), ESP-AFB (Difco Labs, Detroit, Mich.), and MB/Bact (BioMerieux, Durham, N.C.) have reduced time for initial detection of mycobacterial growth to an average of 10 to 13 days. Using the BACTEC system, LJ media could be eliminated without compromising accuracy.¹⁷¹ Final identification can be 4 to 6 weeks longer, but the polymerase chain reaction (PCR) followed by restriction analysis and nucleic acid hybridization has shortened this time to a few days.^{34,155,181,187}

Mycobacterial isolates can have been identified and specialized laboratories determine their susceptibility to antimicrobial drugs. In the United States, some of these laboratories are the National Animal Disease Laboratory in Ames, Iowa, and the National Jewish Medical and Research Center in Denver, Colo. (see [Appendix 5](#)).

50.1.5.6

Organism Detection

Mycobacterial components are detectable in body fluids such as CSF using enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay. The sensitivity of such methods is much greater than acid-fast staining is to detect organisms in leukocytes. Detection of mycobacterial antigens in sputum by ELISA is more difficult because they are often lost in the processing of such fluids for analysis. MAC organisms have been detected within phagocytes in acid-fast stained fecal smears from animals with GI infections.⁷⁸

Animal inoculation has been performed historically to identify mycobacterial species and those, such as *M. leprae* and *M. lepraemurium*, that are difficult to culture. Laboratory animals such as guinea pigs, rabbits, mice, and hamsters have been inoculated intraperitoneally with suspensions of lymph node, spleen, and granulomas from suspected cases.

PCR can be used on tissue specimens or body fluids to detect or identify mycobacteria that grow slowly or cannot be cultured in the microbiology laboratory. The Direct Test (GenProbe, San Diego, Calif.) targets ribosomal RNA, and the AMPLICOR Test (Roche Molecular Systems, Branchburg, N.J.) targets DNA. Such nucleic acid hybridization methods are best used for specific identification of the organisms found in culture. These methods have been helpful investigating outbreaks because genotyping strains may help determine their pathogenic significance or facilitate epidemiologic tracking of their source. Nucleic acid methods should complement but not replace conventional methods of mycobacterial isolation for detection of infection. These methods have a high sensitivity in identifying mycobacteria when organisms are prevalent in cytologic specimens, but a low sensitivity when organisms are few or unapparent.

Genotyping *M. tuberculosis* isolates is usually done via restriction-fragment-length polymorphism analysis of the distribution of an insertion sequence (IS6110) in different strains.¹⁰ The genome of *M. tuberculosis* also contains many mycobacterial interspersed repeat units which can be distinguished. The detection of these spacers can be used in a process called spacer oligonucleotide typing (spoligotyping). Genotyping offers the advantage of evaluating different isolates for drug susceptibility, epidemiologic tracking, and environmental control purposes.

Infectious Diseases of the Dog and Cat, 3rd Edition

50.1.5.7 Tissue Biopsy

Definitive diagnoses can be made by demonstrating acid-fast organisms within a lesion via biopsy and histologic examination of lesions or by direct smears of exudates or fluids. Although often present in low numbers, intracellular tubercle bacilli are recognized by their clubbed-shape and beaded appearance. *M. tuberculosis* bacilli may be prominent in extracellular locations.¹⁰⁶ In comparison to tubercle bacilli, MAC organisms are generally smaller and present in high numbers within infected cells. The acid-fast staining method is ideal for aspirates of tissue and granulomas and for identifying organisms in bacterial cultures. A modified Dieterle stain was more sensitive in detection of low numbers of mycobacteria in lesions than acid-fast methods.²⁴ Unfortunately, this silver impregnation stains *Nocardia* and *Bartonella* in a similar fashion so that other stains such as acid-fast, which also stains *Nocardia*, must be used. Mycobacteria can also be more specifically identified by direct fluorescent antibody methods or PCR. A high percentage of human patients have positive results based on culture and PCR yet have negative staining results by acid-fast methods. Such acid-fast false negative results may relate to a dormant state shown by *M. tuberculosis* in which an alteration in cell-wall composition develops with persistence of infection.¹⁶⁸

50.1.6 Pathologic Findings

In dogs and cats, generalized emaciation is a frequent finding on gross necropsy. Multifocal granulomas are grayish-white to yellow, circumscribed, nodular lesions and appear in many organs. Lung and bronchial lymph nodes are usually the primary lesion sites in dogs, and ileocecal and mesenteric lymph nodes are similarly involved in cats. Generalized spread is more common in dogs than in cats; pleura, pericardium, liver, kidney, heart, intestine, and CNS lesions are the most frequent (Fig. 50-7). The mesenteric lymph nodes, spleen, and skin are more commonly involved in cats. Rarely, bone, joint, and genital lesions may be observed in dogs and cats, and conjunctival lesions have been observed in cats and ferrets. Unlike larger solitary primary granulomas, metastatic lesions are frequently small (1 to 3 mm) and multifocal or appear as large clusters of coalescing tubercles in many organs.

Histologically, granulomatous lesions consist of areas of focal necrosis surrounded by infiltrations of plasma cells and macrophages. Evidence of encapsulation is apparent by peripheral layers of densely packed fibroblasts in a thin, fibrous, connective tissue capsule. Calcification of the granuloma is sometimes present; however, liquefaction of the necrotic central caseous portion is rarely, if ever, observed in carnivores (Fig. 50-8). Epithelioid or histiocytic cells usually border the necrotic zone; giant cell formation, which occurs in other species, is uncommon. Short-chained, beaded, slightly pleomorphic, acid-alcohol-fast bacilli may be detected intracellularly in the periphery of necrotic lesions (see Fig. 50-8). Organisms within macrophages and epithelioid cells are usually more numerous in MAC and *M. genavense* infections than they are in infections caused by *M. bovis* and *M. tuberculosis* (compare Figs. 50-9, A and B with Fig. 50-8). Infection with *M. microti*-like variant can result in variable numbers of intracellular bacilli. In contrast, *M. tuberculosis* infections are characterized by extracellular bacilli.¹⁰⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 50-7 Multifocal granulomas in the kidney of a 3.5-year-old male boxer with systemic spread of *M. tuberculosis* infection. (From Lui S, Weitzman I, Johnson GG. 1980. Canine tuberculosis, *J Am Vet Med Assoc* 177:164–167. Reprinted with permission.)

50.1.7 Therapy

Because of the delay in definitive isolation of mycobacteria, treatment should be instituted based on cytologic or histologic diagnosis. Single-drug treatment of any mycobacterial infection of animals is not advised; rather, for best efficacy, combination therapy is always needed (Table 50-4). Antimicrobial resistance may develop when single-agent therapy is used.² At least two, if not three, drugs should be given simultaneously. For additional information on antimycobacterial drugs, see Antibacterial Chemotherapy, Chapter 34, and respective agents in the Drug Formulary, Appendix 8.

50.1.7.1 *M. tuberculosis* Infection

Treatment of human tuberculosis involves several drug regimens, depending on whether the patient has been exposed and whether the subclinical or active disease has been demonstrated. Long-term (6 to 12 months), single-drug (isoniazid) regimens are given prophylactically when exposure with concurrent immunosuppression increases the likelihood of producing active disease. Treatment of active *M. tuberculosis* infection involves the combination of at least two agents for a minimum of 6 to 9 months. In people, the isoniazid-ethambutol-rifampin combination is the most effective course of therapy, although pyrazinamide is being substituted for ethambutol more frequently. Drugs such as these have made human tuberculosis a curable disease, and surgical removal of tuberculous granulomas is no longer required. However, increasing antimicrobial resistance to these drugs is cause for concern and routine treatment of animal infections might contribute to the development of this resistance.

473

474

Fig 50-8 Photomicrograph of a liver from a 2-year-old female German shepherd showing a caseous tubercle with central necrosis, proliferation of histiocytes and fibroblasts in the middle zone, and encapsulation in the periphery (H and E, $\times 100$). Inset: beaded bacilli (acid-fast, $\times 1000$). (From Lui S, Weitzman I, Johnson GG. 1980. Canine tuberculosis, *J Am Vet Med Assoc* 177:164–167. Reprinted with permission.)

(Courtesy Paul Canfield, University of Sydney, Sydney, Australia.)

Similar guidelines might apply when considering treatment of pets (see [Table 50-4](#)). Chemotherapy of spontaneous canine tuberculosis has been successful in certain cases in which it has been provided. Rapid regression of experimentally produced lesions in dogs has been achieved by combined IV administration of rifampin and isoniazid and intramuscular administration of streptomycin for 23 months. Increases in coagulation times and liver enzyme activities were side effects of this extended therapy. Other drugs that have been shown to have activity against tuberculous mycobacteria are fluoroquinolones, metronidazole, oxazolidinones, azithromycin, and clarithromycin.

The decision to treat infected dogs and cats must be taken seriously because of the obvious human health hazard that exists, particularly when *M. tuberculosis* or *M. bovis* is responsible. It is not recommended for confirmed infections. Diagnosis by skin or serologic testing is not as reliable in detecting exposed or latently infected animals, and placing dogs or cats exposed to human or bovine tuberculosis on prophylactic chemotherapy may be desirable.

50.1.7.2

M. bovis Infection

M. bovis is resistant to pyrazinamide. Cats with *M. bovis* infection have been treated effectively by surgical excision of localized skin lesions and oral rifampin at 4 mg/kg/day for 2 to 5 months and by using long-term protocols including rifampin, a fluoroquinolone, and either clarithromycin or azithromycin.^{47,69} Unfortunately, use of rifampin alone has the potential to induce bacterial resistance.

Infectious Diseases of the Dog and Cat, 3rd Edition

50.1.7.3 *M. microti*-like Infection

Cats with *M. microti*-like infections have been treated successfully in some cases with a combination of rifampin, enrofloxacin or marbofloxacin, and clarithromycin or azithromycin (see [Table 50-4](#)).⁶⁹ Given that single cutaneous lesions have the most favorable prognosis, assessing the cat for evidence of disseminated infection before starting treatment is important. Thoracic radiography is a valuable diagnostic aid for this purpose. Cats with disseminated infection may still respond to treatment but usually require more prolonged courses (longer than 6 months).

50.1.7.4 *M. avium* Complex Infection

Unlike opportunistic rapid-growing mycobacteria, MAC strains are often resistant in vitro to the quinolones and a large number of other antimicrobials. Treatment of dogs with MAC infection has not been very rewarding; however, in most cases, advanced, disseminated visceral infection occurred before diagnosis. One dog was treated with a combination of clofazimine, ciprofloxacin, and rifampin with limited success.¹⁴⁰ Anemia and hepatotoxicity were side effects of rifampin therapy. A basset hound with disseminated infection that was on continuous combination therapy of enrofloxacin, clarithromycin, and clofazimine (dosages as outlined in [Table 50-4](#)) was in remission for 2 years before experiencing relapse.¹⁹ In another basset hound, this same regimen was successful in halting progression of the disease and no relapse had occurred in 2.5 years.⁶³ A third basset hound developed a CNS granuloma during posttreatment remission with enrofloxacin, clarithromycin, and clofazimine, and the progression of the intracerebral lesion was halted by substitution of rifampin with clarithromycin as a better CNS-penetrating drug.⁶³ In human patients with AIDS, the three-drug regimen of rifabutin, ethambutol, and clofazimine is more effective compared with rifampin, ethambutol, clofazimine, and ciprofloxacin.¹⁷⁰

In cats, localized or cutaneous infections have been treated with more success. One cat with a localized MAC granuloma had surgical removal alone, but the mass subsequently returned.¹⁷⁵ A cat with localized MAC infection was successfully treated with surgical removal of a portion of the mass followed by combination therapy with clofazimine and doxycycline.¹⁰¹ Another cat treated with clofazimine alone following surgical debulking had complete remission.¹²³ In another cat with cutaneous infection, treatment with enrofloxacin alone was unsuccessful.¹³⁹ An Abyssinian cat with disseminated infection involving the mesentery and lungs was successfully treated with a combination of clofazimine, clarithromycin, and doxycycline at dosages in [Table 50-4](#).⁶³ Clinical resolution of the problem occurred within 2 months, and treatment was continued for 7 months until hepatotoxicity was heralded by anorexia and marked increase in serum alanine aminotransferase activity. Substituting enrofloxacin for clarithromycin solved this problem, and treatment was continued for an additional 3 months at which time it was discontinued. No relapse occurred during an additional 12 months of monitoring. Several Abyssinian cats with disseminated MAC infections were successfully treated using clofazimine and clarithromycin in combination.^{8,122} Appropriate therapy for potentially resectable granulomatous masses should involve excision of the majority, if not all, of the lesions, when possible, followed by multiple drug therapy. With pulmonary dissemination, effectiveness of therapy can be monitored by repeating thoracic radiography for a clearing of the lung fields (see [Fig. 50-6, C](#)). Abdominal ultrasonography is best for monitoring resolution of mesenteric lesions.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 50-4 Dosages of Some Antimicrobial Drugs for Treatment of Slow-Growing Mycobacterial Infections

DRUG	SPECIES	DOSE (MG/KG) ^a	ROUTE	INTERVAL (HOURS)	TOXICITIES
<i>M. tuberculosis</i> infection					
<i>Chemoprophylaxis</i> ^b					
Isoniazid	D	10 ^c	PO	24	Hepatotoxic
<i>Treatment (minimum of two of the following drugs in combination)</i> ^d					
Isoniazid	D	10–20 ^e	PO	24	Hepatotoxic
Rifampi(ci)n	D	5–10 ^f	PO	12–24	Hepatotoxic; discolors mucosae, tears, and urine
Ethambutol	D	10–25	PO	24	Optic neuritis
Dihydrostreptomycin	D	15	IM	24	Ototoxic
Pyrazinamide ^g	D	15–40	PO	24	Hepatotoxic, GI signs, arthralgia
<i>M. microti</i>-like, <i>M. terrae</i> Group, and <i>M. simiae</i> Infections^h

	C	8–10	PO	24	Orange staining
	C	25 mg total	PO	24	Orange staining
Rifampi(ci)n	B	10–15	PO	24	Hepatotoxic, cutaneous erythema
Doxycycline	B	5–10 ^k	PO	12	Vomiting, esophagitis

D, Dog; C, cat; B, both; PO, by mouth; IM, intramuscular.

a Dose per administration at specified interval. After daily dosing for weeks to months, switch to twice weekly administration for 6–9 months. See also [Appendix 8](#). See [Table 50-2](#) for general susceptibility guidelines and recommended combination therapy for each organism.

b For 6–12 months.

Infectious Diseases of the Dog and Cat, 3rd Edition

- c Dosages are extrapolated from human child and adult recommendations. Treatment of *M. tuberculosis* or *M. bovis* infections is not recommended for dogs and cats.
- d *Localized*: isoniazid and rifampin daily for 6 months with pyrazinamide added during the first 2 months or isoniazid and rifampin alone for 9 months. *Disseminated*: isoniazid and rifampin, with ethambutol or pyrazinamide, or both, initially and treat daily beyond 9 months.
- e Maximum 300 mg daily.
- f Maximum 600 mg daily.
- g Ineffective for *M. bovis* strains.
- h Treatment for 2 months minimum with three drugs in combination (e.g., rifampin with a fluoroquinolone [either enrofloxacin or marbofloxacin] and with either clarithromycin or azithromycin). Maintenance therapy for 4 months thereafter consists of the same dosages of any two of the three drugs.⁶⁹
- i Some large cats require higher doses.
- j Because of difficulty of fractionating liquid in capsules, for convenience cats are usually given one 50-mg capsule per dose. The contents of capsule may be cut into halves with a scalpel blade while wearing disposable gloves and dividing it into two gelatin capsules. Alternatively a compounding pharmacist can provide the optimal dosage size. Currently not available in the United States.
- k Can increase dosage up to 10 mg/kg for improved efficacy but only if this level is tolerated; give with food or administer water to avoid esophageal injury; if possible use monohydrate salt to minimize gastrointestinal irritation.

50.1.7.5 Other Slow-Growing Mycobacteria

Enrofloxacin, rifampin, and clarithromycin, in combination, were effective in treating a cat with localized *M. terrae* complex infection⁷⁴ and another with disseminated *M. simiae* infection.⁴⁹

50.1.7.6 Adjunctive Therapy

In vitro and in vivo, phenothiazine drugs inhibit mycobacterial growth.⁴ Levels that were effective were greater than what could be achieved therapeutically. However, these drugs concentrate in macrophages and may potentiate antimycobacterial agents. Use of low daily levels of a drug such as acepromazine may be considered as adjunctive therapy to help facilitate antimicrobial efficacy. Immunotherapy with avirulent mycobacteria, such as *M. vaccae*, has been advocated to treat people with tuberculosis; however, results in controlled trials have not been effective.⁴³ Low antiinflammatory dosages of glucocorticoids have been given to immunocompromised people with *M. avium* infection when antimicrobial treatment has failed.⁵⁰ Fever and malaise were reversed, and new opportunistic infections were not noticeably increased.

50.1.8 Prevention

Tuberculosis is a major human public health problem. People are susceptible to *M. bovis*, *M. tuberculosis*, *M. microti*, and MAC organisms. This susceptibility is important with respect to control in animals. Identification of *M. tuberculosis* infection in people should be followed by serologic testing or clinical evaluation of pet

Infectious Diseases of the Dog and Cat, 3rd Edition

contacts as possible reservoirs. Outbreaks of *M. bovis* infection in cattle should also be followed by evaluation of dogs and cats on the farm. Feeding of unpasteurized milk or raw offal to pets must be discontinued. Live BCG vaccine has been administered to protect people against infection with *M. tuberculosis*. Live recombinant DNA vaccines have been produced using nonvirulent mycobacteria. The effectiveness of such products is being evaluated on an experimental basis. The attempt to control tuberculosis in dogs with modified live vaccines has had moderate success in that some dogs have shown increased resistance to infection, but immunity is partial, and vaccination has not been generally recommended. This approach also can produce false-positive skin test results as it does in other species.

Table 50-5 Comparison of Available Environmental Disinfectants for Mycobacteria^a

DISINFECTANT	CONCENTRATION	ADVANTAGES	DISADVANTAGES	COMMENTS ^b
Glutaraldehyde	2%	Noncorrosive; active in presence of organic matter	Expense, harmful vapors, contact irritation	20 min at 20° C Manual precleaning Final alcohol rinse
Iodophors	50–100 ppm	Minimal irritation	Stains contacted materials; organic matter decreases activity	Moderate activity, increased with dilutions
Alcohols	70%–90%	Inexpensive	Weakens glues, damages rubber and plastics	Rapid evaporation, limits contact time
Chlorine	1000 ppm	Inexpensive	Weakens certain materials, toxic with acids; ineffective in hard water in presence of organic matter	Common for water system disinfection; less active at hot water temperatures
Hydrogen peroxide	6%	For nebulizers, inhalation equipment	Expensive, may damage certain materials	Mucosal irritation after use for endoscopy

ppm, Parts per million.

- a Nontuberculous mycobacteria such as *M. avium*–complex organisms may be more resistant to environmental inactivation compared with *M. tuberculosis* and *M. bovis*.
- b Contact times for disinfection as outlined by U.S. Food and Drug Administration are 45 minutes at 25° C. Final rinses with alcohol and drying are recommended for most equipment in contact with tissue or mucosae to remove the irritating chemicals.

Handling of saprophytic mycobacteria-infected dogs or cats is not a major health risk for immunocompetent people because these bacteria are normally found in the environment in large numbers. However, they do pose a risk for immunodeficient people and animals. As compared with other pathogenic bacteria, mycobacteria are among the most resistant organisms to disinfection, elevated temperature, or ultraviolet light. Disinfection efficacy depends on the chemical used, its time of application, concentration, and duration of contact. Instruments that contact mucous membranes should be treated with the utmost care to avoid inadvertent transfer of organisms to uninfected patients. Instruments that will contact tissue surfaces must have a high level of disinfection yet be nonirritating. Table 50-5 summarizes appropriate disinfectants and their properties. Glutaraldehyde at 2% should be used for 10 minutes at 20° C. Ethyl and isopropyl alcohols are mycobactericidal agents that can be used as the terminal rinse in disinfection. Regardless of the disinfectant used, manual precleaning with neutral detergents has the greatest effect in decontaminating equipment that has been in contact with mycobacteria. Tap water should never be used as a final rinse to remove disinfecting agents.

Infectious Diseases of the Dog and Cat, 3rd Edition

50.1.9 Public Health Considerations

50.1.9.1 Tuberculous Mycobacteria

Although *M. tuberculosis* and *M. bovis* infections are not maintained in canine and feline reservoirs, infected dogs and cats may serve as temporary sources for dissemination of bacteria into the environment. Because respiratory or intestinal secretions may be contaminated, it is recommended that *M. tuberculosis*-infected animals be either treated or euthanized. *M. tuberculosis* infections have developed in animals in zoologic

476

gardens.^{135,137,143,150} Zoos are a major public health concern because of the unique value of the exhibited animals and their close contact with zoo personnel and visitors. Animals in these exhibits acquire their infection from people they contact. However, spread from the animals back to human personnel has not been documented.^{135,150} Although *M. bovis* infections have been frequent in New Zealand, infected cats did not appear to be a major risk to their owners.^{46,47} Nevertheless, owners should be advised that this organism is a known transmitted pathogen. *M. microti*-like infections in cats are probably acquired from hunting infected prey species; therefore restriction of this activity is the only known preventive measure. This species is not known to infect people. However, occasional cases of human infection with closely related *M. microti* have been reported.¹⁴⁸

477

50.1.9.2 Nontuberculous Mycobacteria

Because they are soil saprophytes, MAC organisms are just as likely to be acquired from environmental sources by people as by pets. Infections with saprophytic mycobacteria, MAC and *M. microti*-like, are the appropriate ones to treat in companion animal practice.^{71,96,101,140} However, to avoid any potential concern, families with members who are immunocompromised should generally be advised not to keep *Mycobacterium*-infected pets.

50.2 FELINE LEPROSY SYNDROMES

Richard Malik

M. Siobhan Hughes

Patricia Martin

Denise Wigney

The term *feline leprosy* is used to refer to a mycobacterial disease in which single or multiple granulomas form in the skin or subcutis in association with large numbers of acid-fast bacilli (AFB), which microbiologists are unable to culture using standard methods. The condition was first recorded in the literature by Australian and New Zealand researchers in the early 1960s.^{115,194} Since then, the disease has been reported in Western Canada, the Netherlands, France, the United Kingdom, and United States.¹⁹⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

50.2.1 Etiology

50.2.1.1 Historical Perspective

Historically, the causative agent of feline leprosy was purported to be *M. lepraemurium*. This bacterium causes murine leprosy, a systemic mycobacterial infection of rats. Cats are thought to contract *M. lepraemurium* following bite injuries from infected rodents.¹⁶³

M. lepraemurium is a fastidious, slow-growing mycobacterial species that can be cultured with difficulty from large inocula on Ogawa's egg yolk medium under strictly controlled conditions or in enriched liquid medium at a critical pH (6.0 to 6.2).^{*} Although a few investigators have successfully grown *M. lepraemurium* from infected cats, the basis of ascribing this bacterium as the etiologic agent of feline leprosy was dependent on transmission studies and the results of delayed hypersensitivity reactions to ID-injected tissue extracts. Several groups were able to show that material obtained from feline lesions can be used to transmit disease to rats, and subsequently back to cats.^{115,117} In such studies, the incubation period varied from 2 months to 1 year or more. Interestingly, among cats, some had a higher degree of susceptibility than others.

^{*} References: 7, 100, 147, 149, 151.

50.2.1.2 Current Perspective

Molecular methodologies have been used to investigate presumptive feline leprosy. Data from such studies have revealed that a large number of different organisms are responsible for what is called the *feline leprosy syndrome*. Of eight cases of invasive or disseminated cutaneous mycobacterial disease investigated by Hughes and colleagues⁸³ using material collected largely from New Zealand cats, four were shown to have *M. lepraemurium* infections. Of the remaining cats, one had a disseminated *M. avium* infection, the cause in one cat was undetermined, and in two cats, infection was attributable to a novel mycobacterial species. In a reappraisal of Australian feline leprosy cases, cats could be divided into two groups on the basis of the patient's age, lesion histology, clinical course, and sequence of 16S rRNA PCR amplicons obtained from lesions.^{84,124} One syndrome in young cats was caused by *M. lepraemurium* and another in immunosuppressed elderly cats was caused by a single novel mycobacterial species. Other investigators found a third novel organism responsible for a lepromatous infection in cats from western North America.^{5,131}

50.2.2 Epidemiology

Feline leprosy is more common in certain geographic locations such as the North Island of New Zealand, the Netherlands, and British Columbia. Furthermore, feline leprosy appears to be more prevalent in temperate coastal areas and port cities, as opposed to inland or tropical habitats.

50.2.3 Clinical Findings

According to the literature, cats with feline leprosy have typically been young adults (younger than 5 years of age), with a preponderance of males. Presumably these patient characteristics reflect the need for the cat to

Infectious Diseases of the Dog and Cat, 3rd Edition

interact with a rat to become infected. The initial lesion is a focal granuloma of the subcutis. Owners become aware of solitary, or more commonly multiple, painless, raised, fleshy, tumorlike lesions, from a few millimeters up to 4 cm in diameter. These granulomas are freely movable over underlying tissues. Lesions can develop rapidly and, when large, may ulcerate. Infection spreads to adjacent areas and may invade underlying tissues and drain to regional lymph nodes. Lesions can occur anywhere but tend to be concentrated on the head and limbs. Small lesions are occasionally found on the tongue, lips, and nasal plane. Lesions, even if multiple, tend to be initially concentrated in one region and have the propensity to recur following excision. In some cases, widespread cutaneous lesions develop.

50.2.3.1

M. lepraemurium Infection

This disease generally occurs in young cats (typically younger than 4 years of age), which initially develop localized nodular disease affecting the limbs. Lesions progress rapidly and sometimes ulcerate (Fig. 50-10).

477

Sparse to moderate numbers of AFB can be identified using cytology or histology, typically in areas of caseous necrosis and surrounded by pyogranulomatous tuberculoid inflammation. Organisms do not stain with hematoxylin and range from 2 to 6 μm (usually 2 to 4 μm). *M. lepraemurium* can be diagnosed based on the sequence of a 446 bp fragment encompassing the V2 and V3 hypervariable regions amplified from lesions using PCR and mycobacterial primers. Based on gene sequence data, *M. lepraemurium* shows greatest nucleotide identity with *M. avium* subsp. *paratuberculosis* and *M. avium*. The clinical course of *M. lepraemurium* infections is aggressive, with a tendency towards local spread, ulceration, recurrence following surgery, and development of widespread lesions over several weeks. Cats tend to reside in suburban or rural areas where contact with other cats is likely.

478

Fig 50-10 Ulcerated *M. lepraemurium* lesions on the forelimb of a young cat. (Courtesy of Peter Ihkre, University of California, Davis, Calif.)

50.2.3.2

Novel Mycobacterial Infection

A second group of *feline leprosy* cases occurs in old cats (older than 9 years) with generalized nodular skin lesions (Fig. 50-11) associated with multibacillary lepromatous histology.¹²⁴ Some cats initially have localized disease that subsequently becomes widespread, while others have generalized disease from the outset. Disease progression is protracted, typically taking months to years, and skin nodules do not ulcerate. Microscopically, lesions consist of sheets of epithelioid macrophages containing large to enormous numbers

Infectious Diseases of the Dog and Cat, 3rd Edition

of AFB, 2 to 8 μm (mostly 4 to 6 μm), which stain also with hematoxylin (Figs. 50-12 and 50-13). A single unique sequence spanning a 557 bp fragment of the 16S rRNA gene can be identified in lesions from these patients. The sequence was characterized by a long helix 18 in the V3 region, suggesting the new species is likely to be a fastidious, slow grower. The 16S rRNA sequence has greatest nucleotide identity with *M. leprae*, *M. haemophilum*, and *M. malmoeense* and contained an additional “A” nucleotide at position 105 (the only other mycobacterial database sequence with the same extra nucleotide being *M. leprae*). A very slow, pure growth of a mycobacterial species was observed on LJ medium (supplemented with iron) and semisolid agar in 1 of 3 cases in which culture was attempted at a reference laboratory.¹²⁴ The environmental niche of this new mycobacterial species has yet to be determined, although the preponderance of cats from rural or semirural areas suggests it is a saprophyte found more commonly in these locations than in metropolitan environments. The organism may normally reside in soil or stagnant watery environments that favor the proliferation of saprophytic mycobacteria and subsequently become inoculated into the subcutis through contamination of traumatic injuries (from cats or native wildlife) or via a biting arthropod.

Fig 50-11 Granuloma on the hock of an 11-year-old, FIV-negative Persian cat infected with the novel mycobacterial species. Although this was the largest lesion evident, numerous similar lesions were present elsewhere over the integument. (Courtesy Richard Malik, University of Sydney, Sydney, Australia.)

The establishment or spread of infection with the novel mycobacterial species suggests a requirement for decreased immunologic surveillance to permit the development of disease with an organism of limited virulence. Furthermore, the etiopathogenesis needs to account for the absence of young cats among this cohort of patients. The presence of a foamy histiocytic infiltrate of the dermis and subcutis in human patients with mycobacteriosis is observed almost exclusively in association with profound immunodeficiency such as that seen with terminal HIV infection. Feline leprosy caused by the novel mycobacterial species may similarly represent a manifestation of deteriorating immune competence in elderly cats with longstanding FIV infection, and indeed one half of the cats so far tested in Australia have been FIV positive. Decreased cellular immunity associated with renal disease may also predispose cats to infection, as renal disease is common among infected cats. Alternately, renal disease may occur as a consequence of the mycobacterial infection, as it does in rats with disseminated *M. lepraemurium* infection, presumably as a result of immune

478

479

Infectious Diseases of the Dog and Cat, 3rd Edition

complex deposition in glomeruli. Thankfully, these infections seem quite sensitive to antimycobacterial therapy.^{81,124}

Fig 50-12 Biopsy material from a cat with novel mycobacterial species. Negatively stained bacilli are evident individually and in bundles, predominantly within macrophages (DiffQuik®, ×1000). (Courtesy Patricia Martin, University of Sydney, Sydney, Australia.)

Fig 50-13 Biopsy material from a cat infected with the novel mycobacterial species. Macrophages laden with abundant intracellular AFB appear pink as a result of taking up the carbol fuchsin stain. The AFB are often grouped in ovoid bundles (acid-fast, ×1000). (Courtesy Patricia Martin, University of Sydney, Sydney, Australia.)

Infectious Diseases of the Dog and Cat, 3rd Edition

50.2.3.3 Feline Multisystemic Granulomatous Mycobacteriosis

To make matters even more complex, work by Appleyard and Clark⁵ and Matthews and Liggitt¹³¹ has demonstrated a third mycobacterial syndrome in cats from western Canada and the United States (Idaho and Oregon) called *feline multisystemic granulomatous mycobacteriosis*. This disease is caused by slow-growing taxa provisionally called *M. visibilis* that gives rise to diffuse (rather than nodular) cutaneous disease and widespread dissemination to multiple internal organs. Sequence analyses demonstrate a large number of nucleotide differences between *M. visibilis* and both *M. lepraemurium* and the novel species reported by Hughes and colleagues.⁸⁴

50.2.4 Diagnosis

50.2.4.1 Microscopic Appearance

Diagnosis of the *feline leprosy* syndromes is usually straightforward, provided that the clinician has a high index of suspicion for the condition. Needle aspirates, crush preparations of biopsy material and histologic sections stained with Ziehl-Neelsen (ZN) or similar methods contain easily demonstrable AFB surrounded by variable granulomatous to pyogranulomatous inflammation. In DiffQuick® (Baxter Diagnostics, Bellevue, Wash.) or Geimsa-stained smears mycobacteria can be recognized by their characteristic negative-staining appearance of slender rods located within macrophages and giant cells (see Fig. 50-12). In smears or sections stained with modified acid-fast stains such as ZN or Fite's stain, organisms take up the pink carbol fuchsin and are acid-alcohol fast (see Fig. 50-13).

50.2.4.2 Bacterial Isolation

Material should also be submitted also for culture, because occasionally slowly-growing species such as MAC and *M. geneavense*⁸² and the tubercle bacilli (*M. bovis* or *M. microti*³²) can produce an identical clinical presentation. In such animals, optimal antimycobacterial therapy can be selected more readily on the basis of in vitro susceptibility results and information available in the literature. *M. lepraemurium* cannot be cultured easily or quickly and is best detected using PCR, and the same is true for the novel mycobacterial species.

50.2.4.3 Nucleic Acid Detection

In the majority of cases, conventional mycobacterial culture gives a negative result caused by the fastidious nature of the causal organisms. Thus a mycobacterial etiology can only be proven using molecular techniques such as PCR amplification and nucleotide sequence determination of gene fragments, as described previously. PCR has the additional advantage of providing a rapid diagnosis. Fresh (frozen) tissue delivered to a diagnostic laboratory with mycobacterial expertise and PCR facilities provides the optimal sample, although freeze-dried specimens may be more conveniently sent when tissues need to travel long distances. Sometimes PCR can be performed successfully on formalin-fixed paraffin-embedded material, although fixation conditions invariably cause some DNA degradation that may limit the success of the procedure. Recently, Hughes and colleagues⁸⁴ have developed specific PCR assays to diagnose infections caused by *M. lepraemurium* and the novel species.⁸⁴ Furthermore, use of a simple restriction enzyme digest allows these assays to distinguish *M. visibilis* strains also.

Infectious Diseases of the Dog and Cat, 3rd Edition

50.2.5 Pathologic Findings

Pathologically, feline leprosy has been subdivided into two forms based on the number of visible AFB present (multibacillary versus paucibacillary), which corresponds with the host immunologic response (lepromatous versus tuberculoid, respectively). Because the causal mycobacteria are slow-growing organisms capable of intracellular survival, the histologic picture depends on the host's immune response. When this response is poor, lepromatous (multibacillary) disease develops with infiltration of the dermis with large sheets of *incompetent* foamy macrophages containing an enormous number of organisms. AFB are usually arranged in the cytoplasm of macrophages as dense parallel accumulations, which displace the nucleus to an eccentric position. Lymphoid cells and plasma cells are virtually absent from the lesions. If the host's immune response is more effective, histiocytic cells are accompanied by a moderate number of lymphoid cells and plasma cells and multiplication of the organism is limited—the so-called tuberculoid response. The tuberculoid form accounts for perhaps two thirds of the cases in western Canada, a large proportion of cases in New Zealand and the Netherlands, but a minority of the cases encountered in Australia.¹²⁴ Invasion of local nerves, a prominent feature of human leprosy, is rarely observed in patients with feline leprosy, although a report described a cat without skin lesions which had mycobacterial infiltration of one sciatic nerve.¹⁵²

50.2.6 Therapy

The existence of multiple diseases, rather than one, clearly has important implications for prevention, diagnosis, and therapy of feline leprosy. For example, most authors recommend wide surgical excision as the treatment of choice for focal lesions.¹⁹⁵ This option is practical in *M. lepraemurium* infections, at least when cats are treated in a timely manner when lesions are localized. On the other hand, although surgery may have a place in reducing the bulk of particularly large lesions in infections caused by the novel mycobacterial species, medical therapy with a combination of drugs generally represents a better first line of treatment.

Only a few cases have been treated, with a documented organism established by PCR, to provide definitive treatment guidelines. Although *M. lepraemurium* and the novel species can be cultured in vitro, isolating these organisms is currently not routine or reliable because of their slow growth and fastidious requirements. Determination of in vitro susceptibility data for individual isolates is therefore not possible.

Only limited experimental studies have been undertaken to determine effective drug therapy for *M. lepraemurium* in vitro or in vivo, and, as yet, data only for the novel mycobacterial species are limited. In one report,¹⁵⁷ the minimum inhibitory concentration (MIC) for rifampin of two strains of *M. lepraemurium* was 4 and 8 µg/ml, levels that should be just obtainable in vivo based on extrapolation from pharmacokinetic studies in people and dogs. Other drugs shown to have activity against *M. lepraemurium* in vitro include ansamycin compounds (rifabutin) and sulpha drugs. Substantial evidence exists that clofazimine has efficacy in vivo, although it is likely that clarithromycin would also be effective based on its wide spectrum of activity against slow-growing mycobacterial species.¹⁵³

The literature suggests that when *M. lepraemurium* infection is diagnosed early, while disease is localized, wide surgical excision of infected tissues provides the best chance to simply and rapidly effect a cure.¹⁹⁵ Aggressive resection techniques should be adopted, with en bloc resection of all lesions, and reconstruction of resulting tissue deficits using appropriate surgical techniques. An approach such as this one should be combined with adjunct antimicrobial therapy beginning a few days before surgery so that effective levels of drugs are present in blood and tissues intra- and postoperatively to ensure primary intention healing.

479

480

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 50-6 Drug Dosages for Treatment of Lepromatous Mycobacterial Infections^a

DRUG ^b	SPECIES	DOSE ^c	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Clofazimine ^d	C	25–50 mg/cat	PO	24–48	≥8
	C	8–10 mg/kg	PO	24	≥8
Clarithromycin	C	62.5 mg/cat	PO	12	≥12
Rifamp(ic)in	C	10–15 mg/kg	PO	24	≥12

PO, By mouth; C, cat.

- a Surgical removal is the most effective therapy. For medical therapy use at least two drugs to include clarithromycin, rifampin or clofazimine.
- b For specific information about each drug consult Drug Formulary, [Appendix 8](#).
- c Dose per administration at specified interval.
- d Because of difficulty of fractionating liquid in capsules, cats are usually given one 50-mg capsule per dose. Alternately, the contents of capsule may be cut into halves with a scalpel blade while wearing disposable gloves and dividing it into two gelatin capsules. Alternatively a compounding pharmacist can provide the optimal dosage size.

Clofazimine, at a dose listed in [Table 50-6](#) given every 24 to 48 hours, has the best reported success rate, although combination therapy using two or more drugs likely will prove superior. Drugs that can be combined with clofazimine include rifampin and clarithromycin, although sulfonamides, doxycycline, new fluoroquinolones such as gatifloxacin, linezolid, or amikacin may in time also prove to be useful. In some patients with advanced disease, the response to treatment is poor.

In feline leprosy cases caused by the novel mycobacterial species, we believe that combination therapy using two or three drug choices of clofazimine, clarithromycin, or rifampin represents optimal therapy. However, we are currently unsure of which drug will prove to be the best combination, and side effects in individual cats may affect which two drugs are used in a given patient. Currently, we recommend a combination of rifampin and clarithromycin as initial therapy. For appropriate dosages and formulating the drugs, see [Table 50-6](#) and Drug Formulary, [Appendix 8](#). Given that clofazimine and rifampin both can produce reversible hepatotoxicity, biochemical monitoring of cats regularly during therapy is mandatory, while vomiting or inappetence (or both) suggests the need for dose reduction or temporary discontinuation of therapy. We have encountered photosensitivity and pitting corneal lesions in some cats during clofazimine therapy. Of these different agents, clarithromycin is the least likely to cause worrisome side effects; however, monotherapy with this agent is not recommended because of the possibility of resistance developing during treatment.

Guidelines for duration of therapy are hard to define, although mycobacterial infections should be generally treated for several months and continued for at least 2 months (the life of a macrophage in the tissues) after disappearance of lesions.

Treatment has been attempted only in one cat with *M. visibilis* infection, which was cured using clofazimine and clindamycin.⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

50.3 CANINE LEPROID GRANULOMA SYNDROME (CANINE LEPROSY)

Richard Malik

M. Siobhan Hughes

Patricia Martin

Denise Wigney

50.3.1 Etiology

Canine leproid granuloma syndrome (CLGS) or canine leprosy is the most common mycobacterial disease of dogs in Australia. A gene sequence was identified representing a novel mycobacterial agent.⁸³ Although the causal organism (see Nucleic Acid Detection later) has a worldwide distribution, its prevalence in other countries has not been documented. Patients with this infection have one or more nodules in their subcutis or skin but are otherwise well.* The condition was first described in a boxer and a bullmastiff from Zimbabwe in 1973,^{172,173} with similar reports from Australia appearing soon afterwards.^{54,130,193}

* References: [33](#), [55](#), 83, 126, 127, 130, 160.

50.3.2 Epidemiology

CLGS has a wide geographic distribution, with cases recorded from coastal and inland regions of all states of Australia. The causal organism is likely to have a worldwide distribution because the condition has also been reported in New Zealand, Zimbabwe, Brazil, California, and Florida.^{55,63,113} The authors are also aware of unreported cases of affected boxers in New York and foxhounds and other dogs in Georgia in the United States. The condition appears to be especially common in Australia and Brazil.

Interestingly, a strong propensity exists for short-coated breeds to be affected, with boxer and boxer-cross dogs accounting for nearly one half of the cases reported. Despite the fact that CLGS was first reported nearly 30 years ago, its etiopathogenesis has not been fully elucidated. The initial report of the disease by Richard Smith observed that, “lesions appear suddenly and are usually seen on dogs bothered by biting flies.”^{172,173} This finding might suggest that flies or some other biting arthropod, such as midges or mosquitoes, inoculate mycobacteria from an environmental niche into susceptible hosts. The predilection for lesions to develop in regions of the body favored by biting insect vectors, such as the head and particularly the ears, is consistent with this hypothesis, as is the overrepresentation of short-coated, large breed dogs, which are generally housed outdoors.

50.3.3 Clinical Findings

Primary skin lesions consist of single or multiple, well-circumscribed nodule or nodules. These lesions can appear anywhere on the dog, although they are usually located on the head and typically on the dorsal fold of the ears. The nodules are hard, painless, and vary in size from 2 mm up to 5 cm in diameter ([Fig. 50-14, A and B](#)). Small nodules are detected as hard subcutaneous lumps, while larger nodules may show superficial hair loss. Very large lesions may ulcerate.

Infectious Diseases of the Dog and Cat, 3rd Edition

Leproid granulomas are confined to the subcutis and skin and do not involve regional lymph nodes, nerves, or internal organs. Consequently, affected dogs suffer no apparent systemic ill effects. This finding suggests that the causal organism has low pathogenicity or special prerequisites, such as a requirement for low temperature, which permits them to survive and multiply in superficial tissues only. Lesions can be disfiguring and cause irritation, especially when lesions are multiple and secondarily infected with *Staphylococcus intermedius*.

Infectious Diseases of the Dog and Cat, 3rd Edition

50.3.4 Diagnosis

50.3.4.1 Clinical and Pathologic Findings

Diagnosis is usually straightforward, given the distribution of lesions (especially the propensity for the dorsal ear fold to be affected), coupled with the tendency for lesions to be multiple, particularly in an at-risk breed, is strongly suggestive of CLGS. Diagnosis can be confirmed by obtaining specimens of representative lesions for cytologic or histologic examination.³³ DiffQuik®-stained smears from needle aspirates typically demonstrate numerous macrophages with a variable number of lymphocytes and plasma cells and lower numbers of neutrophils. Usually a few-to-moderate number of negatively stained, medium-length bacilli can be detected within macrophages or extracellularly (Fig. 50-15). Histologically, lesions within the subcutis and dermis consist of pyogranulomas composed chiefly of epithelioid macrophages, Langerhans-type giant cells with scattered neutrophils, plasma cells, and small lymphocytes (Fig. 50-16). The number and morphology of AFB in ZN-stained sections are highly variable from case to case. Confirming the diagnosis by culture is impossible because the in vitro growth requirements for this fastidious organism have not been determined. A negative culture result, however, can exclude other mycobacteria as the etiologic agent. The skin surface must be thoroughly disinfected before obtaining specimens for culture because saprophytic mycobacteria can easily be cultured erroneously from dirt present on canine skin.

50.3.4.2 Nucleic Acid Detection

PCR methods using universal and purpose-designed primers designed to amplify regions of the bacterial 16S rRNA gene have been performed on leproid granuloma specimens from dogs.⁸³ Using sequence capture PCR for paraffin-embedded specimens and nested PCR on DNA from fresh tissue specimens, a novel PCR product has been identified with identical sequence over a 350 bp region. Analysis of the partial 16S rRNA sequence supports the notion that the novel species is a fastidious, slow-growing mycobacterium. In total, molecular methodologies identified this proposed novel mycobacterial sequence in material from more than 16 Australian cases of CLGS, indicating that the species represented by this sequence is probably the principal causative agent of CLGS.⁸³ Our continuing experience and those of colleagues in California⁵⁵ and

481

482

Infectious Diseases of the Dog and Cat, 3rd Edition

Brazil¹¹³ supports this contention. Interestingly, the species represented by this sequence has never been recorded from mycobacterial granulomas affecting the skin or subcutis of cats, horses, people, or other noncanine mammalian species. Hence no public health risk is believed to exist to the owners of affected dogs.

Table 50-7 Drug Dosages for Treatment of Canine Leproid Granuloma Infection^a

DRUG ^b	SPECIES	DOSE ^c	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Rifampin	D	10–15 mg/kg	PO	24	4–8
Clarithromycin	D	7.5–12.5 mg/kg	PO	12	4–8
Doxycycline ^d	D	5–7.5 mg/kg	PO	12	4–8

PO, By mouth; D, dog.

- a Surgical removal is the most effective therapy. For medical therapy use at least two of the drugs in this table in combination. Topical therapy may also be considered. See text for further information on using topical formulations.
- b For specific information about each drug consult Drug Formulary, [Appendix 8](#).
- c Dose per administration at specified interval.
- d Use monohydrate salt, if available, and administer with food or follow with water.

50.3.5 Therapy

Very little has been written concerning the treatment of CLGS. Many cases are self-limiting, with the nodular skin lesions regressing spontaneously with time, typically within 1 to 3 months of initial appearance. The stated time frame is based on our experiences consulting with veterinarians in relation to cases diagnosed histologically; by the time the sections are submitted, processed, reported on, and a dialogue established with the clinician, lesions have often already started to regress, either spontaneously or in response to antimicrobials (useful for secondary *S. intermedii* but with unlikely efficacy for mycobacteria). This *self-cure* occurs presumably as a result of an effective CMI response mounted by the patient.

In cases with a limited number of lesions, surgical excision can be curative and provides material with which to confirm the diagnosis histologically and using PCR. In other cases, however, the infection progresses to produce chronic, disfiguring lesions that may persist indefinitely. Limited information suggests that treatment with conventional antimicrobial regimens using β -lactam drugs, doxycycline, or a quinolone (as monotherapy) fails to have a significant impact on the course of infection,¹²⁶ although these drugs may be of some benefit by effectively treating secondary pyogenic infections. One report concerning two dogs from Brazil suggested topical antibacterial treatment and orally administered rifampin may be effective.¹¹³ Our experience treating *canine leprosy* suggests that this infection responds to therapy with combinations of antimicrobial agents known to be effective against nontuberculous mycobacteria, including rifampin, clarithromycin, clofazimine, and doxycycline. Based on our evolving experience, a combination of rifampin and clarithromycin given orally at the dosages listed in [Table 50-7](#) is recommended for treating severe or refractory CLGS cases.¹³⁰ Unfortunately, the clarithromycin component of therapy is extremely expensive in large dogs. A far more affordable combination consists of rifampin and doxycycline at the dosages listed in [Table 50-7](#), and further studies may prove this to have similar efficacy to the former regimen. Treatment should be continued until lesions are substantially reduced in size (typically for 4 to 8 weeks) and ideally until lesions have resolved completely. Monitoring hepatic function periodically during treatment is prudent because rifampin may cause

Infectious Diseases of the Dog and Cat, 3rd Edition

hepatotoxicity in some patients. A topical formulation containing clofazimine in petroleum jelly may be used as an adjunct to systemic drug therapy. This formula can be prepared by crushing (with a hammer) 40 50-mg clofazimine *capsules* in a plastic bag; the extracted liquid dye is mixed into an ointment with 100 g of petroleum jelly.¹³⁰ Further work is required to determine the most cost-effective treatment regimen for this condition, and to this end, a topical treatment using multiple chemotherapeutic agents in a permeant vehicle is under development in Australia.¹²²

50.4 INFECTIONS CAUSED BY RAPIDLY GROWING MYCOBACTERIA

Richard Malik

Patricia Martin

Denise Wigney

Sue Foster

50.4.1 Etiology

Rapidly growing mycobacteria (RGM, previously termed opportunistic or atypical mycobacteria) are a heterogeneous group of organisms that produce colonies on synthetic media within 7 days when cultured at 241/4 to 451/4° C (see [Tables 50-1](#) and [50-2](#)). They are distributed ubiquitously in nature and can be isolated from soil, dirt, and bodies of water (including tap water).²⁶ RGM include the *M. fortuitum* group (including *M. fortuitum*, *M. peregrinum*, and the third biovariant complex), the *M. chelonae* and *M. abscessus* group, the *M. smegmatis* group (including *M. smegmatis sensu stricto*, *M. goodii*, and *M. wolinskyi*), and a variety of other species including *M. phlei* and *M. thermoresistibile*. The taxonomy of the RGM has been revised and because of this, the word *group* is used when referring to isolates recorded in early publications.²⁶

In both people and animals, RGM are strongly linked with localized infections of immunocompetent hosts* because the organisms are well adapted to a saprophytic existence and have inherently low virulence for mammals. Thus they do not produce disease unless a breakdown in normal defense barriers provides them with a portal of entry to a favorable tissue environment. RGM are not generally transmitted between hosts. Once introduced, RGM are generally constrained by a vigorous immunologic response that may or may not eradicate them from the tissues but which is effective enough to prevent hematogenous or lymphatic spread. RGM can produce widely disseminated disease but only in severely immunocompromised individuals. They are, however, much less common pathogens in this group of patients than other mycobacterial species, such as the *M. avium* complex.²⁶ RGM produce three different syndromes in cats and dogs: (1) mycobacterial panniculitis, (2) pyogranulomatous pneumonia, and (3) disseminated systemic disease.⁶⁷ In certain dairy herds, RGM are a significant cause of mastitis.¹⁷⁹

482

Mycobacterial panniculitis refers to a syndrome characterized by chronic infection of the subcutis and skin with RGM.¹⁹⁵ This condition is quite common in cats, especially in Australia, and series of up to 49 cases have been reported.^{111,125,129} The condition is less common in dogs.^{68,94,111,128,142} RGM replicate in mammalian tissues when introduced through some breach in the skin, which typically follows penetrating injury, especially when the wound is contaminated by debris or soil. Preference of RGM for fat is a key factor in the pathogenesis of these infections and results in a tendency for disease to occur in obese individuals and in tissues rich in lipid,

483

Infectious Diseases of the Dog and Cat, 3rd Edition

such as the subcutaneous panniculus and especially the inguinal fat pad of cats. Experimental infections cannot be induced in cats that do not have appreciable subcutaneous fat depots.¹¹⁹ Similarly, experimental infections of the ovine mammary gland require instillation of oil in addition to organisms to induce mastitis. The same phenomenon accounts for situations in which RGM give rise to human infections, for example, athletes that inject anabolic steroids in oily vehicles from contaminated multiuse vials, as a complication of lipoid pneumonia, and following augmentation mammoplasty, liposuction, and median sternotomy.²⁶ Adipose tissue offers a favorable environment for survival and proliferation of RGM by providing triglycerides for growth of organisms or protecting them from the phagocytic or immune responses of the host.

Initial reports suggested mycobacterial panniculitis was more common in warm humid climates¹¹¹; however, cats from temperate regions, including parts of Australia, Canada, Finland, and Germany, have subsequently been reported to develop these infections, and RGM can be cultivated from soil samples from Japan and throughout the United States.²⁶ In Australia, the *M. smegmatis* group accounts for the majority of feline cases, whereas it is a much less common cause of equivalent infections in human patients. The *M. fortuitum* group are the predominant pathogens in people.¹²⁹ Interestingly, the swimming pool or fish tank bacillus *M. marinum*, a common cause of subcutaneous mycobacterial disease in people, has not been isolated from feline or canine patients.

Mycobacterial pneumonia has been reported in several dogs^{90,94,182,197} and a few cats.¹⁹⁵ *M. thermoresistibile* caused pulmonary abscessation and pleurisy in a cat.⁵⁷ Insufficient cases have been recorded to identify predisposing factors, apart from a cat examined by Wilkinson in which the infection was thought to be secondary to aspiration of liquid paraffin administered as a fur-ball treatment.¹⁹⁵ In people, as in animals, disseminated infection caused by rapidly growing mycobacteria is uncommon; however, it has been observed in patients with CMI defects or co-infections (or both) with other opportunistic pathogens.³⁶

* References: 26, 87, 111, 129, 195.

50.4.2 Clinical Findings

In cats, infections tend to start in the inguinal region, usually following environmental contamination of catfight injuries (e.g., raking wounds inflicted with the hind claws). The infection may spread to contiguous subcutaneous tissues of the ventral and lateral abdominal wall and perineum. Penetrating injury by sticks, metallic objects, and vehicular trauma may also give rise to these infections, as can cat and dog bite injuries contaminated with soil or dirt. Sometimes infections start in the axillae, flanks, or dorsum and spread into adjacent tissues.¹⁹⁵

Early in the clinical course, infections can resemble catfight abscesses but without the characteristic fetid odor and turbid pus. Instead, a circumscribed plaque or nodule is apparent at the site of injury. Later, the nearby subcutis, to which overlying skin becomes adherent, progressively thickens. Affected areas become denuded of hair and numerous punctate fistulae appear, discharging a watery exudate. Fistulae are intermingled with focal purple depressions, which correspond to thinning of the epidermis over accumulations of pus (Fig. 50-17, A, B, and C). The lesion gradually increases in area and depth and may eventually involve the entire ventral abdomen, adjacent flanks, or limbs. If cats promptly receive veterinary attention, and the lesion is confused with an anaerobic cat bite abscess, surgical drainage and administration of a synthetic penicillin are typically followed by wound breakdown and development of a nonhealing suppurating tract surrounded by indurated granulation tissue (see Fig. 50-17, D). Most cats, even those with extensive cutaneous lesions, have few signs of systemic illness. Some affected cats with severe infections develop constitutional signs; they become depressed,

Infectious Diseases of the Dog and Cat, 3rd Edition

pyrexia, inappetent, lose weight, and are reluctant to move. Occasionally, cats develop the hypercalcemia of granulomatous disease, although this is rarely if ever symptomatic. Surprisingly, other cats remain comparatively well despite extensive disease. The problem usually remains localized to the skin and subcutis. Although adjacent structures such as the abdominal wall can be affected eventually, spread to internal organs or lymph nodes is very unusual.¹⁹⁵

In dogs, RGM infections should be suspected when the clinician is confronted with patients with chronic nonhealing wounds unresponsive to drainage and *conventional* antimicrobial therapy. Lesions typically consist of firm to fluctuant subcutaneous swellings or nodules that ulcerate, drain, and spread centrifugally (with the development of new lesions at the edges of older lesions). Some infections behave differently and instead spread widely to produce multifocal lesions through the entire subcutaneous panniculus. Lesions tend to be neither painful nor pruritic and are generally located in regions subjected to bite wounds or injections, such as the neck, shoulders, flank, or dorsum. A prior history of penetrating injury is common, for example, a bite wound or veterinary intervention (injections, previous surgery). A minority of animals may demonstrate pyrexia, pain, or lameness.^{68,94,111,142}

Dogs and cats with pyogranulomatous pneumonia show coughing, dyspnea, fever, malaise, and often have lost weight because of poor appetite. Young dogs appear to be overrepresented. One patient developed hypertrophic osteopathy secondary to the pulmonary pathology.¹⁹⁷

50.4.3 Diagnosis

50.4.3.1 Sample Collection, Cytology, and Histology

A tentative diagnosis of mycobacteriosis can be confirmed by collection of pus or deep tissue specimens. This material is used to confirm the diagnosis using appropriately stained cytology preparations, histologic sections, and mycobacterial culture. A histologic diagnosis is generally unnecessary if appropriate samples for cytology and culture have been procured.^{125,129} Apprising the laboratory that a mycobacterial origin is suspected is vital so special procedures for processing the specimens can be adopted.

50.4.3.2 Specimen Collection and Submission

In our experience, samples of pus obtained from needle aspirates of affected tissues through intact skin provide the best laboratory specimens in panniculitis cases. This material can be obtained from a palpably abnormal portion of the subcutis. Pockets of fluid can also be visualized using high-resolution ultrasonography, facilitating aspiration. The overlying skin should be carefully disinfected with 70% ethanol before obtaining the specimen to preclude the isolation of saprophytic mycobacteria residing on the skin surface. It may be necessary to carefully move the needle in the subcutaneous space, while applying constant negative pressure, until a pocket of purulent material is encountered. High-resolution ultrasound can be useful in canine patients to identify anechoic foci suitable for aspiration. Aspirated purulent fluid should be submitted to the laboratory for cytology and mycobacterial culture or inoculated immediately into a commercially prepared mycobacteria culture bottle, which is subsequently submitted to the laboratory. Only a small amount of liquid material needs to be aspirated into the hub of the syringe. Submitting the entire syringe to the laboratory after replacing the needle with a sterile cover is easiest. Exudate from draining sinus tracts is heavily contaminated with secondary invaders and represents an inferior sample. If deep biopsies are obtained, they should be titrated in brain heart infusion broth using a sterile mortar and pestle to produce a tissue homogenate suitable for cytology and culture. In animals suspected of having mycobacterial

Infectious Diseases of the Dog and Cat, 3rd Edition

pneumonia, deep bronchial washings, bronchoalveolar lavage specimens, or ultrasound-guided transthoracic fine needle aspirates provide optimal specimens.

Fig 50-17 Inguinal panniculitis. **A**, Inguinal panniculitis caused by *M. smegmatis* in a cat before any therapy. Suppuration from draining sinus tracts is obvious. **B**, Inguinal panniculitis caused by *M. smegmatis* in a cat. Note the “pepper pot” appearance of the skin, caused by draining sinus tracts, some of which are covered by a thin layer of epidermis. The draining tracts are drying out in response to doxycycline therapy. **C**, Panniculitis caused by *M. smegmatis* on the dorsum of a cat. Infection at this site is unusual. **D**, Inappropriate treatment with a penicillin and surgical drainage results in a nonhealing fistulous granuloma. (Courtesy Richard Malik, University of Sydney, Sydney, Australia.)

50.4.3.3 Cytologic Examination

Multiple smears prepared from aspirates of purulent exudate, bronchial washings, or tissue homogenates should be stained using Diff Quik®, Burke's modification of the Gram stain, and a modified acid-fast procedure (decolorizing with 5% sulfuric acid for only 3 to 5 minutes because RGM are not as acid-fast as other mycobacteria). Cytology invariably demonstrates pyogranulomatous inflammation, visualizing gram-positive or acid-fast bacteria, or both, is generally possible (Fig. 50-18), although an exhaustive search of several smears is sometimes required.^{125,129} Organisms often demonstrate beading. Speckled structures or nonstaining *ghosts*, corresponding to poorly staining or nonstaining bacilli, may be observed in smears

Infectious Diseases of the Dog and Cat, 3rd Edition

stained with Romanowsky-type stains⁹⁴ but are much harder to appreciate than in *M. avium* infections, feline leprosy, or canine leproid granuloma cases.

Fig 50-18 Modified acid-fast stain of purulent fluid of a cat with inguinal panniculitis. Note the acid-fast bacilli in the extracellular lipid vacuole. (Courtesy Patricia Martin, University of Sydney, Sydney, Australia.)

484

50.4.3.4

Organism Cultivation and Antimicrobial Susceptibility Testing

485

Tissue homogenates and pus should be streaked onto duplicate 5% sheep blood agar plates and a mycobacterial medium such as LJ medium or 1% Ogawa egg yolk medium and incubated aerobically at 37° C and 25° C, respectively. If available, the BACTEC system (Becton Dickinson Systems, Sparks, Md.) can also be used. Moderate to heavy growth of pinpoint, nonhemolytic colonies is usually detected after 2 to 3 days (occasionally longer) on sheep blood agar at 37° C. When only contaminated specimens are available, tissue homogenates can be treated with 4% sodium hydroxide followed by neutralization with dilute hydrochloric acid before inoculation onto media. Another method that can be used to selectively differentiate RGM from contaminant flora is primary isolation around antibiotic sensitivity disks (first-generation cephalosporins or isoxazoly penicillins) applied to the plate after inoculation. We prefer this method to alkali-pretreatment when dealing with specimens contaminated with staphylococci.

Determining species identification and susceptibility data is of great value in every case because this has a big impact on antimicrobial drug strategies. Species identification can be carried out in a well-equipped veterinary bacteriology laboratory, although sending the strain to a mycobacteria reference laboratory following primary isolation is often more convenient. See [Appendix 5](#) for a listing of specialized mycobacterial laboratories. [Table 50-8](#) contains a summary of information concerning phenotypic features used to identify mycobacteria in the laboratory.

Infectious Diseases of the Dog and Cat, 3rd Edition

MICs for ciprofloxacin, gentamicin, trimethoprim, clarithromycin, and doxycycline can be determined easily using the Etest (AB Biodisk, Solna, Sweden) method.⁷⁵ This methodology is less demanding than is the *gold standard* of broth microdilution. Antimicrobial susceptibility of clinical isolates can also be determined using disk diffusion methodology. Typically, isolates are tested against disks containing representative antimicrobials including doxycycline (30 µg), gentamicin (10 µg), ciprofloxacin (5 µg), trimethoprim (5 µg), tobramycin (10 µg), polymyxin B (300 µg), enrofloxacin (5 µg), and clarithromycin (30 µg). Some antibiotics are included to determine a suitable agent for long-term oral therapy, while others (trimethoprim, polymyxin B, tobramycin) are used to provide phenotypic information concerning strains. Suspensions of each organism in saline or nutrient broth are sown onto sensitivity agar and incubated at 37° C. Results are recorded after incubation for 48 and 72 hours.¹²⁹

Table 50-8 Phenotypic Features That Aid in the Identification of Mycobacterial Species^a

Organism morphology in Ziehl-Neelsen–stained smears of growth taken from Lowenstein-Jensen medium
Colonial morphology (rough or smooth)
Pigmentation when cultivated in the dark or lighted environment
Degree of acid-fastness
Rate of growth at room temperature and at 37° C
Ability to grow at 42° C to 52° C
Arylsulphatase activity at 3 days
Iron uptake
p-amino salicylic acid degradation
Nitrate reduction
β-galactosidase activity
Acid production from carbohydrates (glucose, inositol, mannitol)
Utilization of compounds (glucose, fructose, inositol, mannitol, citrate) as the sole carbon source
Tolerance to 5% sodium hydroxide in Lowenstein-Jensen medium
Susceptibility to polymyxin B, trimethoprim, tobramycin, and other agents

^a In specialized laboratories, a variety of molecular techniques are also used.^{26,129}

50.4.4 Pathologic Findings

Histologically, pyogranulomatous inflammation of subcutaneous adipose tissue, overlying dermis, and underlying abdominal fascia and musculature is noted. AFB may be difficult or impossible to find in ZN-stained tissue sections and are typically located in lipid vacuoles.

50.4.5 Therapy

The management of mycobacterial panniculitis continues to evolve over time according to ongoing clinical experience, availability of new antimicrobial agents, and development of new surgical techniques.^{125,129} Variation in the severity and extent of lesions from patient to patient is great. Difficulty in making a prompt diagnosis is partly responsible for the chronicity, severity, and refractoriness of these infections.⁹⁴ Briefly, treatment should commence with one or more oral antimicrobials (doxycycline, a fluoroquinolone, or clarithromycin) initially chosen empirically but subsequently based on in vitro susceptibility data. Dosages for these drugs are listed in Table 50-9. Long-term administration of such an agent or agents is sometimes sufficient to effect a cure, but in more severe cases, surgical resection of recalcitrant tissues is eventually necessary so that oral antimicrobial therapy will be able to cure the infection permanently. Given the extent and severity of the pathology in many of these cases, understandably, adequate levels of antimicrobials may not be achieved throughout all affected tissues. In these cases, the best chance for a successful outcome is to remove as much infected tissue as possible following preliminary antimicrobial therapy.¹⁵⁶ Residual foci of infection can then be targeted by the high concentrations of antibiotics achieved during and after surgery. Peri- and postoperative antimicrobial therapy is vital to ensure primary intention healing of the surgical incision.

Once a tentative diagnosis of mycobacterial panniculitis is made, immediately starting treatment is desirable. Because positive primary culture takes 3 to 4 days, with an additional similar period required for susceptibility testing, the initial choice of one or more antimicrobials must be guided by retrospectively acquired microbiology data. This data is different in different regions. In Australia, *M. smegmatis* and *M. fortuitum* infections are encountered with similar frequency in companion animals; whereas in the southern United States, *M. fortuitum* and *M. chelonae* infections predominate.^{68,94,111} *M. smegmatis* strains are susceptible to a wide range of antimicrobial agents suitable for treating chronic infections, except for clarithromycin to which a majority of strains show inherent resistance. In contrast, *M. fortuitum* strains generally demonstrate resistance to one or several agents and often have higher MICs for agents to which strains are susceptible, while *M. chelonae* strains tend to be resistant to all common agents available for oral dosing apart from clarithromycin, gatifloxacin, and linezolid.²⁶ In Australia, doxycycline or a fluoroquinolone are thus sensible choices for first-line therapy; whereas in the United States, clarithromycin is the drug of choice for empiric therapy. Recommendations from human infectious disease experts emphasize the possibility of RGM developing resistance to quinolones during a course of therapy.²⁶ Thus using quinolones strategically after surgical debulking or using them initially in concert with another effective antimicrobial may be prudent to reduce the likelihood of resistance developing. Such considerations are said not to be applicable to doxycycline or clarithromycin.²⁶ For this reason, many veterinary dermatologists in Australia routinely use combination therapy with doxycycline and a fluoroquinolone from the outset. Emphasis should be made that, although some RGM strains show in vitro susceptibility to amoxicillin-clavulanate, this drug combination has no efficacy in vivo.

	C	62.5 mg total	PO	12–24	12–52

B, Both dog and cat; C, cat; D, dog; SC, subcutaneous; IM, intramuscular; PO, by mouth.

- a For specific information about each drug consult Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c Monitor blood-urea-nitrogen weekly for evidence of nephrotoxicity; often combined with other drugs. Cannot use long term.
- d Use monohydrate salt, if available; to minimize esophageal irritation give before or with food, or followed by a small amount of water.
- e Must check hemogram weekly for evidence of myelosuppression. Cannot use long term.
- f For the dosage of other quinolones, see Drug Formulary.
- g Avoid in young animals.
- h Avoid higher doses or parenteral use in cats because of risk of retinal toxicity.
- i Because of difficulty of fractionating liquid in capsules, cats are usually given one 50-mg capsule per dose. The contents of capsule may be cut into halves with a scalpel blade while wearing disposable gloves and dividing it into two gelatin capsules. Alternatively a compounding pharmacist can provide the optimal dosage size.

Once susceptibility data becomes available, the optimal drug or drugs are selected. The in vivo response to a drug (or drugs) known to be effective in vitro can then be assessed. In general, using doses as high as possible is necessary because affected subcutaneous tissues are not well perfused, and considerable diffusion barriers prevent blood levels of antibiotics from reaching organisms in fat. Treatment should commence using standard dose rates. Subsequently, the dose is increased slowly (over several weeks) until adverse side effects (inappetence, vomiting) suggest the need for slight dose reduction or until a convincing clinical improvement is observed.

Some animals treated in a preliminary fashion using orally administered agents respond progressively to such an extent that surgery becomes unnecessary. These animals can be cured using medical therapy alone, although treatment with oral antimicrobials for 3 to 12 months may be required. As a generalization, lesions that resolve without the need for further surgical intervention involve a lesser depth of tissues than those that require

Infectious Diseases of the Dog and Cat, 3rd Edition

surgery. Some lesions are so severe, however, that only a limited improvement can be achieved with antimicrobial therapy alone, and surgical intervention is required to affect a cure. Because predicting which cases will require operative débridement is impossible, our recommendation is to start empiric therapy, determine the in vitro susceptibility pattern, then reassess the patient every 3 to 4 weeks to decide if continued improvement is occurring or whether therapy has plateaued and surgery is required.

Preliminary medical therapy is of great benefit because, first, it reduces the amount of tissue requiring resection, and second, it minimizes the possibility of wound dehiscence.

Surgical resection, drainage, or debulking of large pyogranulomatous masses has traditionally been more beneficial in treatment of dogs than it has been in cats. However, recurrence may occur at the wound margins, especially in cats. Obtaining more radical surgical margins has been of benefit in our hands. If surgery is required, a drug with known efficacy against the causal strain that can be administered by injection. For example, gentamicin should be administered intraoperatively (2 mg/kg every 8 hours or 6 mg/kg every 24 hours; IV or SC) and in the early postoperative period (ideally for several days if economically possible). Gentamicin is a good choice because it is bactericidal, available in a parenteral form, inexpensive, and displays good in vitro activity against all RGM. Amikacin is superior to gentamicin, although it is substantially more expensive in Australia.

The critical surgical consideration is to remove as much abnormal subcutaneous tissue as possible (Fig. 50-19), which in some animals may necessitate the removal of very large portions of infected tissue. Severe cases benefit from the radical excision technique developed by Hunt (Fig. 50-20) in which infected tissues are resected en bloc followed by rearrangement of nearby skin to fill the often substantial tissue deficits created.^{87,88} In some cases, however, panniculitis is so extensive that this technique is not feasible. Advanced cases with extensive lesions optimally require the skill of an experienced soft-tissue surgeon to reconstruct the resulting wound without undue tension, particularly in feline cases. The large amount of dead space created by the débridement requires judicious use of latex or closed suction drains for several days postoperatively.

Following surgery, drugs thought to be of greatest theoretical efficacy against the causal organism are used in the postoperative period to ensure that primary intention healing occurs. Residual bacteria at the wound margins are thus targeted by high levels of the effective agent or agents. Because of cost considerations and other practicalities, the choice is generally reduced to one or a combination of a fluoroquinolone, doxycycline, or clarithromycin based on in vitro susceptibility. Dosages for these drugs are listed in Table 50-9.

Infectious Diseases of the Dog and Cat, 3rd Edition

Of the agents suitable for postoperative therapy, the fluoroquinolones (enrofloxacin, marbofloxacin, orbifloxacin, gatifloxacin) and doxycycline are generally the agents of choice for treating RGM infections in Australia, where *M. smegmatis* and *M. fortuitum* strains predominate. In the United States, clarithromycin or fluoroquinolones, or both, represent the cornerstones of therapy for RGM, although doxycycline still has a place in the treatment of susceptible strains.

Fluoroquinolones are bactericidal, penetrate well into tissues (including fat), and are concentrated in polymorphs and macrophages. Current concerns about the retinotoxic potential of enrofloxacin when given to cats in daily doses exceeding 5 mg/kg probably preclude its use in this species, whereas ciprofloxacin, gatifloxacin, or other *veterinary quinolones* may be safer choices at the high doses likely to be required for these infections. However, retinal toxicity may be a potential problem with higher doses of any fluoroquinolones in cats (see Drug Formulary, [Appendix 8](#)). The authors have had no experience using marbofloxacin or orbifloxacin in the treatment of mycobacterial infections, and unfortunately no published data on their use is available. Doxycycline has a cost advantage over the quinolones and, based on our experience, has similar efficacy and is equally suited to long-term oral therapy. Doxycycline monohydrate is the tetracycline of choice for use in small animal patients because it is well tolerated, is present in a readily available form (VibraVet tablets; Pfizer Animal Health, Sydney, NSW, Australia), and has good lipid solubility. This drug is not readily available in many other countries, which is problematic because other doxycycline salts are more irritating, causing vomiting or, worse, esophageal ulceration.¹³⁴ For this reason, doxycycline should be either given immediately before meals with butter or margarine, or it should be followed by a small amount of liquid (see [Appendix 8](#)). Clarithromycin, a macrolide with an extended spectrum of activity and prolonged pharmacokinetics, has proved extremely useful in treating RGM infections in human and veterinary patients. Its major disadvantages is its high cost, which becomes an issue in the treatment of large dogs. Information is insufficient to recommend routine combination therapy in these animals, but the possibility of resistance emerging during therapy should be considered in animals in which a favorable response (especially to fluoroquinolones) is not sustained during a course of therapy or if relapse occurs.

In human infections caused by RGM, single-drug therapy is recommended for localized or minor disease. In contrast, severe or disseminated disease and pulmonary infections usually require multiple antimicrobials, including both IV (e.g., amikacin) and oral medications (e.g., clarithromycin, ciprofloxacin) at least for the first 2 weeks of therapy.

The total duration of therapy should be at least 3 to 12 months. Agents should be administered for at least 1 to 2 months after affected tissues look and feel completely normal. In occasional refractory cases, clofazimine,¹³⁶ cefoxitin, or amikacin may be used for monotherapy or in conjunction with other agents shown to be effective in vitro. Cefoxitin and amikacin can be given only by injection. Several new oral agents for treating refractory RGM infections have become available, including gatifloxacin and linezolid.²⁶ Although these agents hold great promise for some previously untreatable mycobacterial infections, high cost precludes their routine use. We have had limited experience with gatifloxacin in feline patients in which it has proven to be well tolerated and helpful in two refractory cases. This drug has greater activity against *M. fortuitum* and *M. chelonae* strains than older quinolones such as ciprofloxacin.²⁷

In summary, mycobacterial panniculitis is an eminently treatable disease. Diagnosis is straightforward, especially for practitioners familiar with the syndrome. The prognosis is excellent, even in cases with severe, extensive, and longstanding disease. Treatment involves long courses of antimicrobials chosen on the basis of laboratory testing, sometimes combined with extensive surgical débridement and wound reconstruction.

Infectious Diseases of the Dog and Cat, 3rd Edition

Finally, the routine prophylactic use of doxycycline following treatment of penetrating injuries in obese dogs and cats may prevent the development of these deep-seated infections.

487

Similar considerations apply to the treatment of pyogranulomatous pneumonia caused by RGM. Empiric treatment should be started immediately after obtaining diagnostic specimens for cytology and culture. Therapy may need to be altered in the light of susceptibility data. Treatment should initially consist of high levels of two agents known to be effective in vitro, including IV gentamicin and amikacin. Nebulization using gentamicin or amikacin is likely to be a useful adjunct to systemic therapy. Pulmonary lesions that respond incompletely to appropriate medical therapy may need to be surgically resected to affect a cure.*

50.4.6 Public Health Considerations

Rapid-growing mycobacteria are free-living saprophytes; the risk of transmission of these infections between animals or from animal to people is small. However, wound disinfection and contact precautions are usually advised, especially if immunosuppressed people are present in the same environment. Sodium hypochlorite (100 ppm available chlorine) rapidly kills these organisms on contaminated surfaces or inanimate objects.

SC inoculation of *M. chelonae* organisms reportedly occurred through penetration of dog hair into the owner's Achilles tendon by prolonged and vigorous rubbing of the person's ankle on that person's pet terrier.¹³² Tendonitis caused by *M. chelonae* resulted. Cultures of the dog's hair and of tap water from the patient's home were negative for mycobacteria. Human hospital-acquired infections have also occurred. Contamination of multiple dose-injection syringes, peritoneal dialysis and hemodialysis machines, bronchoscopes, and some surgical equipment has led to severe nosocomial infections. Similar problems have not been reported in veterinary hospitals, but the potential exists.

51 CHAPTER 51 Dermatophilosis

Craig E. Greene

51.1 ETIOLOGY AND EPIDEMIOLOGY

Dermatophilosis (cutaneous streptothrichosis) is an exudative skin disease caused by the actinomycete *Dermatophilus congolensis*. Chronic exposure of the skin to trauma or moisture and immunosuppressive therapy or concurrent debilitating diseases may predispose the patient's skin to overgrowth and colonization by *D. congolensis*. This aerobe or facultative anaerobe is a normal dermal inhabitant of numerous mammalian species, including horses, sheep, goats, and cattle. Although not primary hosts, cats^{5,9,12,13} and dogs^{2,6} can be naturally infected. Acquisition from the soil, contact with another carrier animal, or latent infection in an affected animal cannot be excluded in reported cases.

Dermatophilosis has been produced experimentally in dogs after inoculation of the organism onto previously damaged skin¹⁴ and in cats by subcutaneous inoculation.⁹ Trauma associated with insect bites may predispose an animal to or transfer infection. Contamination of puncture wounds is presumed to occur in infected cats.

51.2 CLINICAL FINDINGS

51.2.1 Dogs

Spontaneous dermatophilosis in dogs is confined to the skin. As a primary dermatologic disease, dermatophilosis produces minimal signs of systemic illness, although emaciation and debilitation may be associated with an underlying immunosuppressive disease process. Lesions in dogs are frequently found on haired portions of the skin and consist of dry, adherent scabs that become entrapped in surrounding hair (Fig. 51-1). Removal of the crusts reveals underlying erythematous and ulcerated skin.

51.2.2 Cats

In affected cats, deeper abscesses in muscle, lymph nodes, and subcutaneous tissues have been more characteristic. The lesions are submucosal or subcutaneous pyogranulomas that can produce chronic draining fistulas. Fever, anorexia, and regional lymphadenomegaly or abscess formation are common. Ulcerative granulomas in cats that involve the tongue or urinary bladder have also been described.^{1,13}

489

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 51-1 Skin lesions of dermatophilosis in a beagle. Crusty lesions surround tufts of hair on **(A)** ear margins and **(B)** extremities. (Courtesy University of Georgia, Athens, Ga.)

51.3 DIAGNOSIS

The simplest and most rapid means of establishing a diagnosis involves removing the dried scabs from epidermal lesions or taking biopsy samples of deeper tissues where abscesses are found. Samples are minced in small amounts of sterile saline or nutrient broth. Some of the material is also used to prepare wet mounts or air-dried smears for microscopic examination, and the remainder is submitted for culture. Wet mounts can be stained with new methylene blue; dried specimens are heat-fixed and best stained by Giemsa methods, although Wright and Gram stains are suitable. Exudates or minced preparations usually contain large numbers of neutrophils in clusters around gram-positive branching filamentous organisms. The filaments are recognized by characteristic transverse and longitudinal divisions that result in three to eight paired rows of coccoid spores arranged linearly (Fig. 51-2). Monoclonal antibodies to *D. congolensis* have been used with indirect fluorescent antibody staining to specifically identify the organism in clinical samples.⁸

Sterile specimens from scabs or biopsy samples may be cultured aerobically at 25° C and aerobically or anaerobically at 37° C on solid nutrient agar such as blood or brain-heart infusion media. Small, grayish, raised colonies surrounded by a zone of hemolysis are typically produced. The organism can be more specifically identified by its biochemical properties or after experimental inoculation in laboratory animals. The cocci are vigorously motile when taken from fresh cultures.

Infectious Diseases of the Dog and Cat, 3rd Edition

51.4 PATHOLOGIC FINDINGS

Histologically, the organism produces an exudative, suppurative dermatitis characterized by epidermal hyperkeratosis and subcorneal abscesses with underlying dermal edema and hemorrhage. Branching hyphae and clusters of coccoid bodies are usually in the parakeratotic layer (Fig. 51-3). Hair follicles are minimally affected. In cats the lesions consist of pyogranulomas in subcutaneous tissues or lymph nodes. The organism may be identified by hematoxylin-eosin-stained preparations in the periphery of necrotic lesions. The banded filamentous nature is best demonstrated by Twart's modified Gram stain. Immunostaining with polyclonal bacille Calmette-Guérin antibody has also been used³; however, the procedure is not specific for particular bacteria.

Fig 51-2 Cytologic characteristics of *D. congolensis*. Note filaments of paired rows of cocci, which have a “stacked coins” appearance (Gram stain, ×4300). (Courtesy Emmett Shotts, University of Georgia, Athens, Ga.)

Table 51-1 Drug Therapy for Dermatophilosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)

c Penicillin may be given alone or in combination with gentamicin.

Fig 51-3 Biopsy specimen showing hyphae and individual coccoid organisms within parakeratotic layer of dermis (H and E stain, $\times 400$). (Courtesy Emmett Shotts, University of Georgia, Athens, Ga.)

51.5 THERAPY

Treatment involves keeping the animal's skin dry and hair clipped around the periphery of the lesions or over the entire body if lesions are widespread. Clipping the hair and subsequently bathing with 2% lime sulfur or organic iodine preparations facilitate the softening and removal of the impervious, dry, adherent crusts. Bathing and crust removal should continue for a minimum of 2 weeks.

The infecting organism is susceptible to numerous antimicrobial agents in vitro; however, on the basis of cost and efficacy, penicillin derivatives are the most practical choice ([Table 51-1](#)). Penicillin may be given alone or in combination with an aminoglycoside. Ampicillin or amoxicillin has been administered successfully to treat cats with abscesses.⁵ Tetracyclines have also been effective in treating a cat with an isolate that was not sensitive to penicillins.¹⁰ For dermatophylosis treatment to be successful and permanent, its causes must be found and eliminated.

Infectious Diseases of the Dog and Cat, 3rd Edition

51.6 PUBLIC HEALTH CONSIDERATIONS

People are accidental secondary hosts of *D. congolensis*. People handling infected carcasses or tissues can develop exudative pustular dermatitis.⁴ The disease in people is extremely rare, and approximately 10 cases have been reported in the literature.⁴ Lesions usually consist of multiple white pustules 2 to 5 mm in diameter at the site of contact. These lesions neither spread nor coalesce but resolve within 2 weeks or more rapidly if the lesions are opened to drain.

52 CHAPTER 52 Abscesses and Pyogranulomatous Inflammation Caused by Bacteria

Craig E. Greene

52.1 ABSCESSSES

52.1.1 Etiology and Pathogenesis

Abscesses, which are characterized by an accumulation of pus, can occur in almost any tissue ([Table 52-1](#)). Percutaneous abscesses are the most common bacterial infections of feline skin and probably the most common site of abscess formation in dogs and cats. The following discussion will focus on feline abscesses, although the principles of diagnosis and treatment are similar in any location. See infections in the various system chapters for a discussion of abscesses in these locations. Abscesses develop more frequently in cats than they do in dogs, owing to the tough, elastic nature of feline skin, which readily seals over contaminated puncture wounds, causing the accumulation of subcutaneous exudates. Sharp teeth and fighting behavior, especially of adult males, are important predisposing factors to abscess formation. The size and degree of abscess formation depend on many factors, including the overlying skin tension, amount of dead space, and gravitation of exudate below the point of penetration. Pus-filled cavities that form above the puncture site drain easily. Cavities that gravitate below the puncture site become overdistended and may repeatedly drain through the puncture site without complete resolution.

Because feline abscesses usually result from bites and scratches, the most common organisms found within them are resident oral microflora ([Table 52-2](#)).^{*} Although more difficult to cultivate, anaerobes are more frequently isolated than are aerobes. The supposition that *Pasteurella multocida* is the most common organism involved in cat abscesses is incorrect. Anaerobes can often be isolated in greater frequency. *P. multocida* is likely the most common facultative aerobic organism contaminating cat bite wounds (see [Table 52-2](#)). Cats that sustain bite injuries are more likely to become infected with feline immunodeficiency virus (FIV) (see [Chapter 13](#)).

^{*} References: 7, 8, 14, 15, 23, 25, 32, 34.

52.1.2 Clinical Findings

The clinical signs of abscess formation in cats reflect the site and severity of the infection. Abscesses are usually located around the cat's legs, face, back, and base of the tail ([Fig. 52-1](#)). Some cats have a noticeable swelling with few other signs of illness, whereas more extensive infection is associated with fever (39.7° to 40.6° C [103.6° to 105.2° F]), anorexia, depression, and regional lymphadenomegaly. Pain is usually present at the site of infection, and obvious swelling or warmth may or may not occur. Mature abscesses that are ready to discharge are usually tender with a soft, fluctuant central area. Feline skin easily stretches over distended abscesses. Redness or discoloration is rarely apparent unless the blood vascular supply has been compromised. Drainage of white, creamy, purulent material occurs spontaneously or after surgical lancing. Foul-smelling, red-brown discharges occur, especially with tissue necrosis and virulent anaerobic bacterial infection. Systemic signs often abate once the abscess ruptures, and the only evidence of infection may be matted hair at the site of drainage. Careful examination in the area of swelling usually reveals a small puncture wound covered by a crust. Recurrent abscesses at the same site suggest underlying osteomyelitis or neoplasia, poor surgical drainage, immunodeficiency (e.g., FeLV or FIV infection), antimicrobial resistance, or the presence of a foreign body. Abscesses associated with foreign bodies, underlying osteomyelitis, or certain organisms such as

Infectious Diseases of the Dog and Cat, 3rd Edition

Nocardia or *Mycobacterium* also tend to recur, persist, or spread in tissues (Fig. 52-2). Abscesses in dogs and cats are often associated with noticeable regional lymphadenomegaly. Sometimes the overlying skin may become necrotic, and exudate drains externally (Fig. 52-3).

Additional clinical manifestations reflect various sequelae that can occur. Lameness or paralysis will be apparent with myositis, osteomyelitis, septic arthritis, or discospondylitis. Depression, stiffness, lethargy, nuchal rigidity, or seizures can be seen with meningitis. Osteomyelitis also causes chronic or recurrent draining fistulas that only temporarily respond to antibiotics. Respiratory distress, dyspnea, and stridor are noted with pyothorax, sinusitis, and rhinitis. Vestibular signs can be noted if otitis media or interna develops. Signs of bacteremia and systemic infection include malaise and fever or reflect those of another organ system of hematogenous localization.

Retrobulbar abscess or cellulitis is associated with proptosis, decreased globe mobility, oculonasal discharge, chemosis, conjunctival congestion, protrusion of the third eyelid, pain while opening the mouth, periocular swelling or discomfort, lethargy, weight loss, and fever. Corneal ulcers may develop from exposure keratitis or physical trauma caused by the discomfort. Swelling may be present behind the last upper molar.

52.1.3 Diagnosis

Determining the presence of an abscess is usually based on clinical history and examination. Abscesses should be expected in cats that develop an acute onset of unexplained fever, anorexia, or lameness, even in the absence of an obvious swelling, given that abscess formation may be delayed or hidden. The differential leukocyte count can help in determining the extent of infection and the animal's ability to control it. A low count with an inappropriate shift is associated with diffuse infection or cellulitis. A mature neutrophilia is more characteristic of a walled-off or mature abscess. Severe leukopenia (a cell count of under $4000/\text{mm}^3$), with or without an associated anemia, may be present in cats infected with feline leukemia virus (FeLV) or FIV that develop chronic or recurrent abscesses as a result of immunosuppression. Unlike those in FeLV- or FIV-infected cats, the leukograms usually improve in immunocompetent cats after the abscesses drain.

d Has been reclassified, see Etiology, [Chapter 53](#).

Fig 52-1 Abscess of tailhead from bite wounds in a cat with fever, leukocytosis, and caudal hyperesthesia. The tail was amputated because of severe infection and tissue necrosis. (Courtesy University of Georgia, Athens, Ga.)

Fig 52-2 Recurrent draining tracts over the thoracic region in a cat with a bite wound infection caused by *Nocardia* sp. (Courtesy University of Georgia, Athens, Ga.)

Ultrasonography can be used to view the extent of a swelling and accumulation of fluid or pus in soft-tissue planes.^{3,1a} Radiographic contrast procedures may be helpful in determining the extent or depth of a draining fistulous tract. Injection of contrast via an indwelling Foley catheter can be followed by radiography, computerized tomography (CT) scans, or magnetic resonance imaging (MRI). Cerebrospinal fluid evaluation and radiographic imaging is needed to detect central nervous system abscesses within the cranial vault or spinal canal.^{38a}

Causes of recurrent or nonhealing abscesses in cats include retroviral infections, as previously discussed, underlying osteomyelitis, neoplasia or foreign body, or infection with organisms such as *Nocardia*, *Mycobacterium*, fungi, or parasites such as *Cuterebra*. Chronic or recurrent draining abscesses should be evaluated by radiography for underlying osteomyelitis, by cytology and culture for possible fungal or unusual bacterial infection, or by surgical exploration for the presence of a foreign body or parasite. Culture of abscess wounds for bacteria is not generally indicated because surgical débridement and empiric antimicrobial therapy are often effective. Anaerobic bacteria are difficult to culture.

Fig 52-3 Abscess of cervical lymph node with drainage in a dog caused by a stick puncture wound injury of the oropharynx. *Actinomyces* sp. was isolated. (Courtesy University of Georgia, Athens, Ga.)

52.1.4 Therapy

Abscesses vary in severity and in the extent of therapeutic intervention required. Small, localized abscesses that drain spontaneously by the time animals are presented for examination require that the hair around the wound be clipped, and the margins of the wound should be cleaned. Should abscesses not be open, surgical drainage and débridement may be needed. Whether opened naturally or by surgery, the cavity should be flushed with hydrogen peroxide, dilute chlorhexidine, or dilute iodophor solutions. More extensive infections that cause signs of systemic illness may require antibiotic administration, surgical drainage, or supportive care.

52.1.4.1 Antibiotic Therapy

Antibiotic therapy has a decided but not absolute role in the management of abscesses in cats. Although mortality and complications resulting from abscesses have been reduced with the use of antibacterials, these agents should not be given indiscriminately or in the absence of other adjunctive measures. Antibiotics alone are ineffective in penetrating walled-off abscesses that require drainage. Empiric antibiotic therapy should be discontinued and extensive diagnostic investigation initiated if abscesses or fever persist longer than 1 to 2 weeks or reform after repeated surgical drainage.

Infectious Diseases of the Dog and Cat, 3rd Edition

Penicillin derivatives are antibiotics of choice for treating abscesses because they are bactericidal and have marked activity against the more frequently encountered organisms ([Table 52-3](#)). Penicillin V, amoxicillin, or ampicillin may be dispensed in oral formulations to be administered by the client. However, amoxicillin or ampicillin may not always be as effective as penicillin is in treating anaerobic infections. Because of a similar antibacterial spectrum, chloramphenicol can be substituted for penicillin, but it is bacteriostatic and frequently causes anorexia; it can also be hazardous to people. If anaerobes are suspected, penicillin, second- or third-generation cephalosporins, chloramphenicol, clindamycin, and metronidazole have the greatest efficacy. Certain *Fusobacterium* spp. have also been susceptible to erythromycin and doxycycline (see also Therapy, [Chapter 41](#)).³³ *Rhodococcus* has been primarily susceptible to aminoglycosides, chloramphenicol, and erythromycin (see also Rhodococcal Infections, [Chapter 35](#)).¹⁵ Topical application or direct instillation of antibiotics into the abscess cavity is ineffective because, with the exception of nitrofurans, none work in the presence of pus. Hydrogen peroxide or chlorhexidine solutions and nitrofurazone powder or solution are empirically placed in surgically opened abscess cavities without documented efficacy. Systemic antibiotic therapy may be beneficial in minimizing abscess formation when given immediately after bite wound contamination or with diffuse cellulitis (see also Bite Wound Infections, [Chapter 53](#)). Within 24 hours of injury, a single injection of procaine penicillin G can thwart the development of an abscess.²⁴ Although therapeutic drainage has been advocated for most abscesses, medical therapy alone has proved efficacious in treating affected people.⁴ Antimicrobial treatment of abscesses in cats may be considered when surgical intervention will alter delicate anatomic structures or will involve considerable anesthetic risk. Less favorable outcomes are associated with large (over 5 cm) lesions or with mixed bacterial populations.⁴ Without surgical drainage, medical therapy must be continued for longer periods of at least 14 to 28 days.

493

494

Table 52-3 Drug Therapy for Feline Abscesses^a

DRUG ^b	DOSE ^c	ROUTE	INTERVAL (HOURS)	DURATION (DAYS) ^d

c Dose per administration at specified interval.

d Treatment is required for at least 14 to 28 days if surgical drainage is not performed.

52.1.4.2

Surgery

Surgical intervention is reserved for mature or ruptured abscesses. Diffuse cellulitis or early abscesses should be allowed to mature before surgical drainage is performed. Applying warm compresses daily or soaking affected extremities in warm, saturated Epsom salt solutions may hasten the maturation process. Both measures have been beneficial in keeping already established drainage sites open until proper healing can

Infectious Diseases of the Dog and Cat, 3rd Edition

occur. Surgical therapy usually involves creating drainage openings at the most ventral portion of an abscess cavity. Controversy exists as to the degree and type of surgical closure indicated. Most veterinarians debride the abscess cavity and remove a small portion of overlying skin to prevent premature closure. Placement of soft rubber tubing that exits at the lowest point of incision with partial closure is frequently used to maintain a drainage opening. A few veterinarians, advocating complete primary closure of the abscess cavity after extensive débridement, argue that more rapid healing and less postoperative drainage are achieved.² Systemic antibiotic therapy is probably essential whenever partial or complete surgical closure is performed because the likelihood of organisms remaining in the wound is high, and the risk of systemic spread increases.

Surgical drainage must be established whenever abscess formation occurs within closed cavities. Retrobulbar abscesses must be drained by passing a probe from immediately behind the last upper molar upward into the retro-bulbar space. Infraorbital abscesses are usually associated with infection of the upper carnassial tooth, which must be extracted. Sinusal, nasal, and chronic middle-ear abscesses also require surgical drainage with débridement of bone because of the loculation of pus within cavities surrounded by bone. Abscesses associated with underlying osteomyelitis must be treated by surgical débridement of infected bone. Foreign bodies or material must be removed from abscess cavities before they will heal.

Castration is recommended as a preventive measure to abscess formation because it reduces the fighting and roaming behavior of male cats. Progestogens can be given similarly to modify behavior, but the necessity of their continued use induces many undesirable side effects.

52.2 FELINE PSEUDOMYCETOMA, BOTRYOMYCOSIS, PYOGRANULOMATOUS INFLAMMATION

A chronic pyogranulomatous inflammatory reaction caused by bacteria and resembling a fungal growth is known as botryomycosis. Literally, the gross appearance of these proliferative growths resembles a bunch of grapes. Eosinophilic infiltration is commonly found. Grossly, the lesions have microabscesses surrounded by fibrous granulation tissue. This funguslike condition is often caused by *Staphylococcus* spp. (presumably, *intermedius*); however, other unidentified rod-shaped bacteria have been observed.⁴¹ Lesions are usually localized masses with embedded yellow-white grains that resemble bacterial colonies (similar to *Actinomyces* or *Nocardia*). These lesions are composed of infiltrating eosinophils and macrophages surrounding necrotic tissue. A large number of saprophytic bacteria and fungi, in addition to staphylococci, can produce similar lesions and must be considered (Table 52-4).

These lesions are thought to be caused by chronic unresolved abscesses. The reason for development of these lesions has not been determined; however, neutrophils surrounding bacterial colonies are replaced by fibrosing granulation tissue later in the encapsulation of the abscess. Only a few cats had positive antibody test results for FIV; none had positive results for FeLV.

Infectious Diseases of the Dog and Cat, 3rd Edition

Lesions are commonly found in the cervical and extremity regions in addition to the abdominal mesentery of cats. Lesions usually develop as localized masses.

Diagnosis of this condition is first made by cytologic examination of exudates. Degenerate neutrophils, macrophages, lymphocytes, plasma cells, and intracellular bacteria (often cocci) will be observed. The grains when squashed on a slide consist of masses of bacteria. Should staphylococci not be isolated, further diagnostic testing should include histopathologic examination and aerobic and anaerobic bacterial culture. Special staining should include methenamine silver and acid-fast methods.

Treatment involves surgical removal and drainage of infected tissues. Antibacterial therapy by itself is usually futile; however, it can be helpful as an adjunctive measure. Long-term antimicrobial therapy for up to 4 months is often needed. Methicillin-resistant staphylococci have been cultured or suspected as the cause of this condition; thus antimicrobial therapy may require prior culture and susceptibility testing.

53 CHAPTER 53 Bite Wound Infections

Craig E. Greene

Ellie J.C. Goldstein

53.1 DOG AND CAT BITE INFECTIONS

Veterinarians can be an important source of information for the public concerning animal bites. Approximately 50% of Americans will be bitten by an animal at some point in their lifetime. In addition to the zoonotic concern, dogs and cats frequently bite each other, resulting in injuries that must be treated as emergencies.

53.1.1 Epidemiology of People Bitten by Animals

Animal bite wounds are fourth among the most commonly reported human illnesses each year in the United States. Although it is reported that 4.7 million people are bitten by animals in the United States annually,^{10,34,128,140} less than half of the bites are ever reported and only 18% of the people seek medical attention.¹²³ Bites from animals that are pets are even more drastically underreported. Approximately 90% of animal bites of people are from dogs and cats.¹⁵¹ Approximately 1% (with a range of 0.3% to 1.1%) of emergency hospital visits by people involve bite injuries.¹⁶⁴ Data from Switzerland suggest that similar statistics are found in Europe. Dogs accounted for more than 60% and cats for 25% of all bites inflicted by vertebrate animals.¹⁰⁶

496

Veterinarians and animal health personnel are at greater risk for injury by dogs and cats than the general population.⁹³ Results of a survey of a group of veterinarians in the United States indicated that approximately 65% had sustained a major animal-related injury.⁹³ Animal bites and scratches accounted for 34% and 3.8%, respectively, of the traumas. Dogs were involved in 24% and cats in 10% of the injuries. In their careers, 92% of the veterinarians surveyed had sustained dog bites, 81% cat bites, and 72% cat scratches. The following epidemiologic discussion focuses on bite injuries that are not related to veterinary practice and for which a veterinarian may be consulted to determine the disposition of the dog or cat responsible for the bite. (However, the information can be applied to injuries that occur within a veterinary practice setting.) The procedures for injured people can also be applied to treating wounds of dogs and cats that are bitten during a fight. The characteristics of dog- and cat-related injuries are summarized in [Table 53-1](#).

53.1.1.1 Dog Bites

An estimated 34 million American households own dogs, with a total canine population of 68 million. Dog prevalence varies worldwide, and developing countries have a greater percentage of feral domestic dogs. Risk factors for dog bites include the dog's age, breed, size, medical health, sex, and reproductive status.^{57,97,122,134,167} Bites are more likely to be delivered by reproductively intact male, large-size (greater than 22.7 kg [50 lb]), 6-month-old to 4-year-old dogs that are mixed breeds, German shepherds, or chow chows. However, breed-specific statements can be inaccurate because of breed popularity and misidentification, inaccurate estimates of a breed's prevalence, and differences in aggressive behavior.

Infectious Diseases of the Dog and Cat, 3rd Edition

Of the 800,000 annual dog bites in the United States that require medical attention, approximately 20 are fatal.^{8,49, 141,164} Approximately 350,000 emergency room visits related to dog bites occur each year^{10,164}; the number of admissions is second only to baseball and softball injuries as admissions for recreational injuries. Reports citing large dogs as the most frequent biters may underestimate the number of bites from smaller dogs.¹⁶⁷ However, serious bites to children are commonly inflicted by large dogs.^{24,57,97} Regardless of size, dogs can exert a jaw force of 450 psi, enough to do extensive damage to tissues. Additional pulling and tearing can cause shearing injuries. Dogs cited for causing a high percentage of the severe or fatal bites have included pit bulls, Rottweilers, German shepherds, chow chows, cocker spaniels, and huskies.^{112,141,142} However, a study in one Florida county found that golden retrievers and cocker spaniels have bitten more people than German shepherds. In one observation, Labrador retrievers and golden retrievers commonly bit their owners or someone petting them, whereas German shepherds, Bernese mountain dogs, and collies tended to be aggressive to strangers.¹⁰⁷ Dominance aggression has been linked to unprovoked attacks of people by dogs. In one behavior clinic, the most prevalent breeds for which dominance aggression was treated were the English springer spaniel, cocker spaniel, Labrador retriever, golden retriever, Dalmatian, Rottweiler, and German shepherd.¹²³ In addition to breed behavior, another important contributory factor to biting is the degree of responsibility exercised by the animal's owner.

A survey of fatal dog-bite attacks in the United States from 1979 to 1998 listed the pit-bull-type, Rottweiler, German shepherd, husky-type, malamute, Doberman, chow chow, Great Dane, and Saint Bernard as the most prevalent breeds.¹⁴² These data were acquired by searching news accounts and the Humane Society of the United States registry databank. Dog bite statistics from media reports in North America show that up to 77% of 931 dog attack fatalities and maimings resulted from dogs that were pit-bull types, Rottweilers, wolf hybrids, or a mix of these breeds.³³ These data, which may be biased by media interest, show that pit-bull types are the only breed that attack adults as frequently as children; these dogs may lack normal canine inhibition. In contrast, Rottweilers and other breeds attack children 3 times more often than they attack adults, indicating that the children's size may play a role. Wolf hybrids predominantly attack young children (younger than 7 years), suggesting that predation rather than territoriality or reactivity is the reason for their attacks.³³ Some are concerned that data from news services may sensationalize and bias reported incidents.¹²³ Furthermore, the data on fatal attacks should not overshadow the medical importance of nonfatal bite injuries, which likely do not have the same breed bias. Lastly, dog owners can play a significant role in increasing or decreasing aggressive pet behaviors by the socialization of their dogs and the way they handle aggressive behaviors. No dog is born aggressive, but it can become aggressive through improper discipline and training. Therefore veterinarians should emphasize and support educating their clients about aggressiveness and legislation directed at controlling undesirable animal behaviors or negligent owners.¹¹⁰ Legislation on breed-specific prohibitions is unlikely to be legally enforceable.¹⁶² Veterinarians should always report aggressive incidents that happen during a pet's hospitalization to the pet's owners and others handling the involved pets (Table 53-2).

Less than one half of dog bites are provoked; males and children are more likely to be involved in provoked attacks.¹²⁴ Most dog bites involve a dog owned by the family or a neighbor, and they are often unprovoked. For example, fatal dog bites of newborns often occur when infants are sleeping. The majority of cat bites are provoked, and females and adults are more likely to be bitten.

Other factors involved with dog bites include the person bitten, the dog-person relationship, and the setting.¹⁶⁸ Approximately 75% of bite injuries are in people younger than 21 years, with peak incidence at 5

Infectious Diseases of the Dog and Cat, 3rd Edition

to 9 years. Children are more likely to provoke dogs and often do not understand the dog's body language. Reports of the high prevalence of bites among children may be related to the additional attention given to dog bites of children compared with those of adults. Although males comprise approximately 65% of all those bitten, boys and girls younger than 6 years account for almost 60% of all fatal bite injuries. More than 50% of injuries among children occur on the head, face, or neck. *Any* movements in the presence of *certain* dogs can cause the dogs to become aggressive, especially when children are involved.^{104,134} Bending over, reaching toward, hugging, or grabbing the collar of a dog are typical human behaviors that may increase the risk of being bitten, especially if a dog is afraid, possessive, or dominant. Other kinds of dog aggression and their eliciting behaviors are discussed elsewhere.^{168,170}

In general, people are more likely to be bitten by a dog if they own a dog, they are in the presence of a dog owned by someone else, or the dog lives in a household with at least one child.^{57,104,167} Recipients of reported bites are more likely to be neighbors of families who own dogs, with the next likely recipients being the owners, although bites to owners are probably underreported.^{24,170}

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 53-1 Epidemiologic Characteristics Associated with Dog- and Cat-Related Bites or Scratches

CHARACTERISTICS OF CATS AND DOGS EXHIBITING AGGRESSION		
	CATS	DOGS
Age	Insufficient data	Less than 5 years (49%)
Sex	Female (67%)	Male (70%–79%)
Ownership Status	Stray (57%)	Owned (a significant number of these owned aggressive dogs live in a household with at least one child)
Reproductive Status	Insufficient data	Intact (not neutered)
Size	Insufficient data	Large dogs (> 50 lbs)
Breed	Insufficient data	Total annual # bites: mixed breed and German shepherds Bite rates: German shepherds and Chow-Chows. Highest rate of severe/fatal bites: pit bulls, German shepherds, Chow-Chows
CHARACTERISTICS OF PEOPLE INJURED BY CATS AND DOGS		
	VICTIMS OF AGGRESSION BY CATS	VICTIMS OF AGGRESSION BY DOGS
Age	25–34 years	< 20 years old, with significant occurrence in 5–9 years old
Sex	Females (59%)	Males (62%)
Relationship to animal	Victim does not own cat	Victim is family member or acquaintance to the owners Dog's owners are most frequently bitten by dogs – not necessarily by their own dogs (family's dog-30%; neighbor's dog-50%)
CHARACTERISTICS OF THE INJURY EVENT		
	COMMON CAT-BITE SCENARIO	COMMON DOG-BITE SCENARIO
Kinds of aggression	Fear-related aggression, play aggression, redirected aggression, "biting and petting syndrome"	Dominance aggression, possessive aggression, fear-related aggression, protective/Territorial aggression, punishment-induced aggression, pain-elicited aggression
Time of Year	May through August (warm weather)	May through August (warm weather)
Time of Day	9:00 am to noon	Late afternoon
Other Factors	If the cat is owned, 50% of the victims are the owners	Unusually high incidence of bites by chained dogs who are restrained on their own property
Typical wound characteristics	80% of all bites require medical attention 50% of all wounds become infected 29% of all cat-bite victims return to doctor after initial visit due to complications Wounds consist of scratches (70%); punctures (27%) and tears (3%) to finger (21%), arm (18%), foot or leg (8%), face or neck (7%); and multiple body locations (3%).	20%–60% of all bites require medical attention Insufficient data on number of wounds that become infected 5% of all dog-bite victims return to doctor after initial visit due to complications Wounds consist primarily of puncture and tears to the extremities (76%) and to face (15%), 70% fatal injuries to children < 9 yrs old. Highest death rate to neonates (< 1 month old). Death rates of neonates 295/100 million; for children 1–11 months old 47/100 million
LOCATION OF BITE WOUNDS ^a		
	CAT BITES (%)	DOG BITES (%)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 53-2 Recommendations for Limiting Dog Bites

Animal Health Professionals

1. Use extra caution when handling pit bulls, Rottweilers, wolf hybrids, and chow chows.
2. Separate aggressive dogs from one another, and protect handling personnel. Provide leashes and carriers.
3. Always muzzle dogs with known or suspected aggressive tendencies.
4. Use a metal choke collar and chain leashes on aggressive dogs.
5. Snap bolt cages or runs containing aggressive dogs. Place signs on cages and runs to identify aggressive dogs.
6. Always have two people in a room when handling or working around aggressive dogs.
7. Educate clients on pet selection, conditioning, and handling.

Dog Owners

1. Avoid selecting dog breeds with known aggressive tendencies.
2. Do not bother ill animals or those who are eating, sleeping, or nursing pups.
3. Socialize dogs at an early age.
4. Take dogs to obedience classes when they are pups.
5. Have pets neutered, especially males.
6. Always supervise children when pets are present.
7. Never leave any dog alone with an infant or a child.
8. Select dog breeds based on known bite tendencies.
9. Never take a pet with a history of aggression into a household with children.
10. Be sensitive to children's fears of pets, and delay or avoid acquiring one until they are comfortable.
11. Spend time with a pet before taking it home.
12. Teach dogs submissive behavior when they are being reprimanded or fed.
13. Immediately notify your veterinarian if your dog shows aggressive tendencies.
14. Never pet a dog until it has had time to see and sniff you.
15. Do not play aggressively with dogs or stare at them directly.
16. Teach children not to approach unfamiliar dogs without allowing the pets to smell them first. When reaching out to a dog, the child should present a balled fist to keep fingers protected.
17. Children should not disturb sleeping dogs or run and scream around them.

Infectious Diseases of the Dog and Cat, 3rd Edition

18. If a dog becomes aggressive, children and adults should remain motionless, avoid direct eye contact, and if knocked over, lie curled up and motionless.

19. Report all bite incidents to adults or proper authorities.

Community Efforts

1. Disseminate information to children and parents.
2. Provide bite prevention courses in schools and for parent organizations.
3. Institute animal control laws and enforcement.
4. Target chronically irresponsible dog owners rather than specific breeds.

Other factors that can affect a dog's likelihood of biting include whether the dog is chained for long periods,⁵⁷ geographic location, time of year, time of day, and weather. A majority of dog bite injuries occur between April and September, when warm weather is conducive to outdoor activity (see [Table 53-1](#)).¹⁶⁷ A booklet on bite prevention is available at www.statefarm.com/consumer/dogbite.htm or www.avma.org. Additional information on dog bite prevention can be found at www.hsus.org. Information concerning variations in dog bite statutes in the United States has been reviewed.⁶⁸ An excellent review on the community approach to dog bite prevention was published in a report by an American Veterinary Medical Association task force.⁹

In a study of dog bites involving caregivers in a veterinary teaching hospital, caregivers interacting with older dogs were more likely to be bitten than those interacting with younger ones.⁴³ Dogs with a propensity to bite already had warning signs posted on their cages.

53.1.1.2

Cat Bites

Compared with dog bites, much less has been reported about feline aggression (biting and scratching) toward people. Approximately 400,000 cat bites are reported each year in the United States, and cat-induced wounds have a greater propensity for becoming infected than dog-induced wounds. Cat bites constitute 5% to 25% of animal-related injuries in people, whereas other domestic and wild animals account for less than 1% of reported bites.

The most commonly reported cat bites and scratches involve unowned female cats that have injured adult women (see [Table 53-1](#)). Scratches and bites are more common in warm weather (the summer season) and the late afternoon. Cat-induced wounds have been described as being scratches, punctures, or tears.¹⁶⁶ Owned cats have bitten people on the neck, face, and multiple sites, whereas strays are more likely to injure the hand. Older people are more likely to be bitten on the hand.

53.1.1.3

Bite Wounds

Of the injuries for which medical attention is sought, it is estimated that between 4% to 20% of dog bite wounds and 20% to 50% of cat bite wounds become clinically infected.¹⁵¹ Clinical infections usually occur within 8 to 24 hours after injury. Dog bite injuries may result in significantly more functional impairments, although cat bite wounds have a greater risk of developing a progressive infection.⁹⁶ The small incisors of

Infectious Diseases of the Dog and Cat, 3rd Edition

cats cause deep punctures that can penetrate underlying bones, connective and muscle tissues, and joints. Most bite infections are minor; however, at least 10% require suturing, and between 1% and 5% result in hospitalization.¹⁶³

The infecting organism in bite or scratch injuries usually corresponds to the normal oral microflora of dogs and cats (Table 53-3; compare with Table 89-1), although organisms from the environment or skin around the injury may also contaminate the wound. Bite wounds are usually polymicrobial, with a median of five isolates per wound comprising three aerobes and two anaerobes.^{42,151,152} Although greater than 80% of cultures produce pathogens, only 15% to 20% of bite wounds become clinically infected.⁶¹ The risk of infection is highest (approximately 40%) for crush injuries, puncture wounds, wounds in areas of preexisting edema, and hand wounds.⁶⁰ Despite the numerous aerobic and anaerobic organisms that contaminate bite wounds, only a few such as *Pasteurella multocida*, *Eugonic fermenter-4a* (EF-4a), and *Capnocytophaga canimorsus* consistently cause systemic manifestations. In the past the role of strictly anaerobic bacteria in bite wounds has been overshadowed by such notorious genera as *Pasteurella*. However, with modern methods of anaerobic cultivation, the role of these bacteria in bite wounds has been realized. When present, anaerobic bacteria are usually isolated in mixed cultures. *Fusobacterium* species, *Bacterioides* species, *Porphyromonas* species, *Prevotella* species, and other anaerobic gram-negative bacilli are often involved.^{4,91} *Erysipelothrix rhusiopathiae* has been isolated from dog and cat bites.^{1,151} An unusual form of motor neuron disease suspected to be caused by a virus occurred after a cat bite.⁸⁰

The public health aspects of rabies, tetanus, and bartonellosis are discussed in Chapters 22, 43, and 54, respectively. People who have been bitten may have to be hospitalized if they develop significant local or systemic infections; are unresponsive to oral antibiotics; have penetrating wounds of tendons, joints, or the central nervous system (CNS); have open fractures; have significant blood loss or airway injuries; require reconstructive surgeries; require wound elevation; have head or hand injuries; or are immunocompromised.¹⁶³

53.1.1.4 Bacteria Relatively Unique to Dog and Cat Bites

Bite wounds caused by dogs and cats may contain some unique bacteria that have not been previously identified in people. Although some such as *Pasteurella* organisms are commonly found in animal bite wounds, others such as *Riemerella anatipetifer* in the cat mouth and *Bacteroides tectum*, which is found in cat and dog bites, are unique to these animals. *Eikenella corrodens*, a pathogen often found in wounds caused by human bites, has been reported once each as a result of a dog bite and a cat bite.¹⁵¹ Unfortunately, some of the unusual isolates may not be responsive to conventionally used antibacterials.

53.1.1.4.1 Pasteurella

Pasteurella organisms are small, nonmotile, gram-negative, bipolar-staining bacilli that are clinically significant in many dog- and cat-bite wounds. These organisms normally inhabit the nasal, gingival, and tonsillar regions of approximately 12% to 92% of dogs and 52% to 99% of cats, as well as many other animals. *Pasteurella* species have been reclassified based on their DNA homology. *P. multocida* ssp. *multocida* and ssp. *septica* have been the most common isolates from clinically healthy cats, whereas *Pasteurella canis* has not been frequently isolated from healthy dogs.^{20,108} This same distribution is found with bite-associated infections. Strains isolated from cats were more commonly pathogenic (71%) than those from dogs (8%). *P. multocida* ssp. *multocida* and ssp. *septica* have been isolated in more serious or

Infectious Diseases of the Dog and Cat, 3rd Edition

systemic infections caused by biting or licking of wounds by dogs or cats.^{76,121} The frequency of isolation is as follows: in cat wounds, *P. multocida* is 50% and *P. septica* is 30%; in dog bite wounds, *P. canis* is 27%, *P. multocida* is 13%, and *Pasteurella septica* is 13% (see Table 53-3).⁶² Isolation of *Pasteurella dagmatis* is rare.³⁸ Although many cats and dogs harbor *Pasteurella* organisms in their saliva, the risk of infection in people is low if they have not been bitten.¹³⁸

Although dog bites account for more than 80% of emergency room visits related to animal bites, cats are responsible for approximately 75% of bites or scratches contaminated with *Pasteurella*. More than 50% of all cat-bite wounds and 20% to 30% of all dog-bite wounds are contaminated with *Pasteurella*.⁹⁶

Pasteurella infections also have been reported after bite injuries caused by large exotic Felidae. Scratch injuries from dogs are less likely to cause *Pasteurella* infections than cat scratches, unless the scratch is also associated with a bite injury.¹⁰⁵ Cats frequently lick their paws and usually hiss when they scratch, thereby producing aerosolized secretions that contaminate the wounds, which is probably related to the higher incidence of *Pasteurella*-infected scratches. A person who was licked daily on her hands by her

499

dog developed a *Pasteurella* throat abscess after tonsillectomy.⁷⁶ *Pasteurella* meningitis developed in a person with extensive dental caries who regularly kissed the family dog. *Pasteurella* has been isolated from the oral cavity of some people who have kissed their dogs and cats but not from those who have not.^{11,12}

501

Pasteurella acquired from pets may also cause various upper respiratory tract infections, including tonsillitis,¹⁷¹ sinusitis,^{13,116} and epiglottitis.¹³⁹ Submandibular cellulitis (Ludwig's angina) developed in a previously healthy person 10 days after playing with a dog.⁴⁴ *Pasteurella* peritonitis developed in dialysis patients after a cat scratch or bite that penetrated the tubing of their home dialysis machines.⁹⁸ Nontraumatic domestic cat exposure has also been associated with *Pasteurella* peritonitis in people with hepatic cirrhosis.⁸⁹ Joint arthroplasties have become infected with *P. multocida* when people have been bitten by cats.^{23,52}

Most *Pasteurella* infections occur in people who have frequent contact with farm or pet animals. Presumably, bites in people in urban environments are related to dog, cat, or other small animal or rodent exposure.

Although a majority of human *P. multocida* infections are related to animal bites, people also may develop pasteurellosis from general animal exposure. In most of these cases, licking of the human's intact or injured skin by the pet and inhalation or ingestion of animal secretions are the most likely sources of entry. Infections associated with inhaled or disseminated microorganisms frequently localize in the gastrointestinal or respiratory tracts or CNS. Patients who are immunosuppressed or have a predisposing underlying illness such as diabetes mellitus and hepatic dysfunction are more likely to develop bacteremia and die. Meningitis has been reported in infants and children who have been licked in the face by family dogs.¹⁵⁶ Even neonatal puppies may be susceptible to certain virulent strains of *Pasteurella*, presumably acquired from the oral cavity of their dam. A virulent strain of *P. canis* biotype 1 was determined to be the cause of mortality in neonatal puppies with multisystemic infection.⁴¹

53.1.1.4.2

Bergeyella (Weeksella) zoohelcum

Bergeyella (Weeksella) zoohelcum, a gram-negative bacillus previously classified as CDC IIj, is a component of the normal oral flora of dogs, cats, and other animals. Few instances have been reported of infection in people caused by a bite wound from dogs or cats.^{109,151} Abscesses, tenosynovitis, meningitis, and pneumonia have occurred. The organism is susceptible to β -lactam antibiotics, quinolones, and chloramphenicol.

53.1.1.4.3

Eugonic Fermenter-4

EF-4 are unclassified bacteria that are resident oropharyngeal and nasal microflora of dogs and cats. Isolation rates vary, with 30% to 90% of clinically healthy animals having these bacteria.⁵⁴ EF-4 bacteria are more prevalent than *Pasteurella* in the oropharynx of dogs. They can cause severe illness in immunocompromised people or when inoculated into deep bite puncture wounds. EF-4 bacteria have been divided by biochemical features into two biovars, EF-4a and EF-4b, which have different pathogenic potentials.⁶ EF-4a has been isolated from infected dog bite wounds in people and has been associated with deeper or systemic infections in people. In contrast, EF-4b has been found in wounds caused by bites from

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs and cats.¹⁵¹ EF-4b has also been the predominant isolate associated with virulent pneumonia in dogs and cats (see Respiratory Infections, [Chapter 88](#)).

53.1.1.4.4

Capnocytophaga

Capnocytophaga species are capnophilic (carbon dioxide-flourishing), gram-negative, gliding bacteria that are closely related to *Fusobacterium* and *Bacteroides* species. They are commonly isolated from the oral cavity of people and animals. The organisms are divided into two main groups: (1) species from the human oral cavity (*Capnocytophaga ochracea*, *Capnocytophaga gingivalis*, and *Capnocytophaga sputigena*—previously Centers for Disease Control (CDC) biogroup dysgonic fermenter-1 [DF-1]) and (2) species found in the oral cavity of dogs, cats, and other animals (*C. canimorsus* and *Capnocytophaga cynodegmi*—previously CDC biogroup DF-2). In immunocompetent hosts, *Capnocytophaga* can produce various infections including in the respiratory tract, wounds, bone, and abdomen. In immunocompromised hosts, fatal bacterial sepsis can result. *C. canimorsus* is a slow-growing (3 to 11 days in culture), thin, filamentous, non-spore-forming, nonmotile, pleomorphic, facultative aerobic, gram-negative bacillus. It has been associated with fatal septicemia in people, predominantly after dog bites and less commonly after cat bites or scratches.^{102,160} It has been isolated from the oral cavity of 16% and 18% of clinically healthy dogs and cats, respectively.¹⁶³ Many cases with a 30% mortality rate have been reported in the literature. *C. canimorsus* has an unusual propensity to cause systemic bacteremia, presumably because of its tropism for endothelial surfaces and its inherent resistance to serum complement. The majority of *C. canimorsus* infections have occurred in immunocompromised individuals older than 40 years. A veterinarian who had undergone a splenectomy died from an illness after a dog bite. Most people who develop fatal complications of *C. canimorsus* infection have underlying contributing factors, such as cytotoxic chemotherapy-induced or surgical splenectomy, glucocorticoid therapy, Hodgkin's disease, macroglobulinemia, alcoholism, peptic ulcer, arteriosclerotic heart disease, hemoglobinopathy, immune-mediated thrombocytopenia, granulomatous or other chronic lung disease, chronic arthritis, macroglobulinemia, neutropenia, intestinal malabsorption, or old age (older than 65 years). Presumably, the factors caused defects in the phagocytic immune defenses, and the individuals could not eliminate the organism from the blood. As with pasteurellosis, some patients with *C. canimorsus* sepsis have been exposed to dogs, cats, or other carnivores or to outdoor environments but had no known bites.

Ocular keratitis and blepharitis have developed in people who were closely associated with their pet dogs or cats but have also developed in other people with no known animal exposure. Corneal scratch injuries from cats have also produced keratitis in people. Results from DNA hybridization and biochemical studies have shown that the more virulent species isolated from people with septicemia were *C. canimorsus*, and those from localized (noninvasive) wound infections or keratitis were *C. cynodegmi* (DF-2-like). Other *Capnocytophaga* species are part of the normal gingival flora of people and cause problems such as conjunctivitis, periodontitis, gingivitis, abscesses, and body cavity infections.⁴⁶ In addition, they can cause bacteremia in immunocompromised individuals.⁶³ Infections with these other *Capnocytophaga* are not associated with animal exposure.

53.1.1.4.5

Nonoxidizer-1

The nonoxidizer-1 group of bacteria (CDC NO-1) comprises isolates of an unusual bacterium that has been only recovered from people bitten by dogs (77%), cats (18%), and other animals (5%).⁸⁴ The bites were on various parts of the body. Isolates have been described as fastidious, gram-negative pleomorphic

Infectious Diseases of the Dog and Cat, 3rd Edition

rods. The organisms are similar to asaccharolytic strains of *Acinetobacter*. Numerous other bacteria can be isolated from infected wounds; however, isolation of these bacteria appears to be unique to animal bites. Dogs and cats should be considered reservoirs for these bacteria.

53.1.2 Epidemiology of Bitten Dogs and Cats

The incidence of bite wounds in dogs and cats has not been well established; however, estimates are that they comprise approximately 10% and 15% of trauma-related emergencies for dogs and cats, respectively.⁹⁰ As with humans who are bitten, many incidents likely go unreported, and owners do not seek immediate veterinary attention. Dogs can cause puncture wounds, but their strong jaws also tear, lacerate, crush, and avulse bones and soft tissues. Cats with small, thin teeth often produce piercing injuries of deeper tissues. Although open wounds have more immediate tissue injuries, those from deep punctures are more likely to result in deep infections and abscesses with secondary damage.

In one study a majority of dogs bitten were intact males.¹⁴⁶ Bitten dogs often weigh less than the overall population of dogs and have a median weight of 20 kg. Dog bites peak in the warmer months of the year, a similar finding with cat bites (Table 53-4). Small dogs are more likely than large dogs to have thoracic and back lesions (Fig. 53-1). In medium-weight dogs the most common bite sites are the neck, back, and extremities. They have a higher prevalence of back and perineal injuries than small dogs. In large dogs the head and extremities are the most commonly involved sites. Penetrating wounds have been seen in 31% of thoracic bites and 79% of abdominal wounds.¹⁴⁶

53.1.3 Clinical Findings

53.1.3.1 People

The types of injuries caused by dogs biting humans vary and include abrasions, punctures, avulsions, and lacerations. Dog bites cause severe crushing injuries and lacerations with ligamentous tearing and tissue necrosis. A majority of lesions in adults are primarily on the upper extremities and trunk (Figs. 53-2 and 53-3). Young children generally have facial injuries because of their small stature and lack of experience with dogs and because dogs tend to bite the face and mouth when being aggressive. In comparison, dogs biting other dogs most commonly injure the extremities followed by the head, neck, thorax, and abdomen (Fig. 53-4; see Table 53-1).³⁵

Cat bites are deep, and the sharp teeth are more likely than dog teeth to produce wounds that become foci for abscess formation and resultant complications such as sepsis, meningitis, endocarditis, septic arthritis, or osteomyelitis. Cat scratches frequently occur on the handler's arms and hands and usually are associated with attempts to restrain the animal (see Table 53-1). Scratches can become colonized by the same organisms as bites. (See Bartonellosis, Chapter 54, for a discussion of cat scratch disease.)

Signs indicating wound infection include localized swelling or reddening and pain with or without a purulent drainage. The type of organism causing infection and the bite site are the most important factors in determining the clinical course of the injury. The two most clinically significant organisms are *C. canimorsus* and *Pasteurella* species.

Infectious Diseases of the Dog and Cat, 3rd Edition

53.1.3.1.1

Pasteurella Infections

Almost two thirds of infections with *Pasteurella* in people are cutaneous and often caused by bites or licking of wounds or damaged mucous membranes by animals.⁴⁵ Systemic spread or penetration of deeper tissues has caused respiratory infections, septicemia, and urogenital and intraabdominal infections. Bite infections caused by *Pasteurella* organisms are more progressive than those produced by many other bacteria. The time from bite until onset of infection has been 12.3 hours, 15 hours, and 24 hours for streptococci, *Pasteurella* species, and staphylococci, respectively.¹⁵² Usually within 8 to 48 hours, cellulitis develops at the site of injury with *Pasteurella* species infections. Erythema, tenderness, and swelling occur in association with a serosanguineous to purulent, malodorous, dark yellow discharge. Lymphadenomegaly and low-grade fever (less than 38° C [100.5° F]) develop in some patients. Cellulitis can lead to extensive infection of deeper tissues or potentially fatal septicemia. Septicemia is characterized by persistent chills, fever, and collapse. Chronic osteomyelitis, septic or posttraumatic arthritis, tenosynovitis, meningitis, and smoldering abscesses also can develop.⁹⁴

53.1.3.1.2

Eugonic Fermenter-4 Infections

As with *Pasteurella* species, EF-4 organisms have been associated with cutaneous, systemic, respiratory, and intraabdominal infections in people. Their presence in a human infection is generally correlated with close aerosol, salivary, or bite contact with dogs or cats. Otitis externa and media developed in a man whose dogs frequently licked his ears.¹³⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

53.1.3.1.3 *Capnocytophaga* Infections

Although inconsistent, cellulitis is the most common finding associated with bite wounds contaminated by *C. canimorsus* and *C. cynodegmi*. Bite infections caused by *Eubacterium plautii* can appear to be similar to those of *C. canimorsus*.⁵⁶ In some cases, eschariform lesions, characterized by formation of purplish-black necrotic tissue around the bite site, are seen. Patients who have undergone splenectomy or are immunosuppressed, including those with older age or cirrhosis, develop the most severe illness from septicemia, which is characterized by fever, malaise, myalgia, vomiting, diarrhea, abdominal pain, dyspnea, hypotension, thrombocytopenia with purpura, symmetric peripheral gangrene, oliguria, disseminated intravascular coagulopathy, and death.¹²⁶ The fatality rate has been higher than 25%, and acute myocardial infarction has been reported in some people. Regardless of the clinical spectrum, most patients have continuous bacteremia. Localization of the septic process without death can occur, and some people develop endocarditis, purulent meningitis, and polyarthrititis. The organisms may not be demonstrated on microscopic examination of tissues, although they may be found in blood films of some patients with severe bacteremia and in blood culture.

Capnocytophaga isolates may be detected within 72 hours in culture, but 7 to 10 days is typical. Growth is enhanced in the presence of carbon dioxide and with serum-enriched media. The laboratory should be advised when *Capnocytophaga* is suspected so that specific tests can be performed to detect these unusual gram-negative organisms. Because identification of the organisms takes a relatively long time, antimicrobial therapy must be instituted immediately without definitive identification.

53.1.3.1.4 Nonoxidizer-1 Infections

Infections caused by NO-1 appear to be local and result in abscesses or cellulitis. Purulent drainage, hyperesthesia, erythema, and swelling are characteristic. In rare situations, sepsis can develop with fever and chills; however, patients from which this organism has been isolated did not have identified preexisting immunodeficiencies.

53.1.3.2 Dogs and Cats

In the mobile, elastic skin of dogs and cats, bite injuries may be less noticeable or may migrate through deeper tissues and go undetected, whereas animal bite wounds in people are more apparent. As in dog or cat bite injuries of people, the organisms inoculated into dog and cat tissues after bites are the inhabitants of the oral flora. Bacteria come from the local environment, skin surfaces, and the oral cavity. Infections are often mixed and include a combination of aerobic and anaerobic bacteria. Infections may dissect along tissue planes and into deeper body cavities or visceral organs. Many of these subsequent infections may be delayed and go unrecognized until signs of systemic infection are observed. (See [Chapter 52](#) for a discussion of feline abscesses.)

Bite wounds are considered contaminated as soon as they occur. Organisms inoculated into damaged tissue are likely to proliferate and produce considerable infection. Aerobic bacterial flora are the predominant isolates from canine and feline bite wounds ([Table 53-5](#)); however, this is likely a result of inferior techniques in collection and processing of specimens and the additional cost associated with anaerobic culture in clinical practice. Studies that have used fastidious collection and processing of anaerobic specimens have resulted in higher yields.

Infectious Diseases of the Dog and Cat, 3rd Edition

53.1.4 Management and Therapy

53.1.4.1 Animal Bites in Dogs and Cats

53.1.4.1.1 Transport and Evaluation

When possible, owners should be advised on transportation procedures for bitten animals. Hemorrhage from wounds should be controlled with gentle pressure applied to affected wounds using a clean, lint-free, dry compress ([Table 53-6](#)). The animal should be strapped to a large, flat board or wrapped in bedding. Internal injuries are impossible to assess immediately, so it is much better for an initial physical examination to be performed as a baseline evaluation. Bitten animals are often in severe pain, so they should be muzzled during transport. The owner should be advised to bring vaccination documents to the clinic. At that time, obtaining a more complete history of the bite incident will help determine whether the animal needs rabies prophylaxis or special precautions should be taken while handling and observing the bitten patient (see Rabies, [Chapter 22](#), and Compendium, [Appendix 4](#)). Refer to these sources for specific guidelines as published by the American Association of State Public Health Veterinarians and the Centers for Disease Control and Prevention.

a Data compiled from references 67, 39, 152, 32, 86. (These wounds were caused by dogs biting dogs.)

b Data from references cited in Table 52-3. (These wounds were caused by cats biting cats.)

53.1.4.1.2

Diagnostic Procedures

Assessing the animal's vital signs, such as body temperature, pulse, and respiration rate, and performing a general systems evaluation are paramount for stabilizing the traumatized patient. Hypotension from shock, infection, or hypovolemia should be managed with IV fluids; antibiotics and short-term glucocorticoids may be necessary. Physical examination of the site determines the extent of injury to nerves, tendons, or bones. The need for cosmetic repair must be gauged immediately to reduce the amount of scar tissue in

Infectious Diseases of the Dog and Cat, 3rd Edition

the final healing. Chemical restraint or local lidocaine infusion may be needed to better assess and probe the wound. Injuries can include punctures, lacerations, and crush or avulsion injuries. Injuries to nerves, tendons, ligaments, or bones should be evaluated by checking for sensation, mobility, and palpable swellings. A diagram or photograph of the injury may be valuable. A radiograph may detect underlying bony injuries or the presence of a foreign body such as a tooth and can serve as a baseline for evaluation of potential osteomyelitis in the future.

Cultures and Gram stains are helpful if signs of local drainage or regional lymphadenomegaly are present. Signs of infection are usually apparent beginning 12 to 24 hours after the injury. For cultures, areas around the wounds should be clipped with a number 40 clipper blade followed by cleansing with chlorhexidine and the procedure outlined in [Table 53-6](#). Culture swabs are satisfactory for open wounds, whereas tissue aspiration is best for deep puncture wounds.

505

Table 53-6 Evaluation and Care of Bite Wounds: Tips for Veterinarians

Dog or Cat Bitten by Animal

Obtain animal information

History of injury

1. Identify species of biting animal. If wildlife species, obtain biting animal or its body or head if possible.^a
2. Note time bite occurred.
3. Note behavior of biting animal or provocation causing bite.

Physical examination of injuries

1. Measure and classify depth, tissue damage, and risk for cosmetic damage and infection.
2. Determine range of motion and extent of muscle and tendon swelling.
3. Perform neural exam for sensory function and motor response.
4. Evaluate circulation by assessing warmth and color.

Diagnostic measures

1. Obtain baseline radiographs if injury is over bone.
2. Obtain cultures of wounds (optional).
 - a. Aerobic: culturettes with transport media^b
 - b. Anaerobic: culturettes with reducing media^c
3. Cytologic or Gram stain evaluation of exudates is essential.
4. Perform complete blood count or chemistry panel if anesthesia is warranted.
5. Provide rabies booster (see [Chapter 22](#) and [Appendix 4](#)).

Treatment

1. Clip the hair away with a #40 clipper blade.
2. Cleanse with antiseptic scrub to skin edges surrounding wound.
 - a. Chlorhexidine^d
 - b. Povidone-iodine^e
3. Flush wound with copious amounts of soap and water, saline, or both.
 - a. 18-gauge needle or tubing on 35–50 cc syringe or fluid bag
 - b. Lavage: 8 psi to facilitate bacterial cleansing

Infectious Diseases of the Dog and Cat, 3rd Edition

c. Isotonic warm Ringer's or saline solution

d. Disinfectant solution of chlorhexidine^d or povidone-iodine^e

4. Prepare wound with surgical debridement of devitalized structures.

5. Close wound only under special circumstances (see text).

6. Cover wound with bandage or sterile water-based ointment.

7. Give antimicrobial therapy (prophylactic if indicated by depth or severity).

8. Immobilize and elevate wound.

9. Provide staged debridement with periodic application and removal of adherent bandages.

53.1.4.1.3

General Management

Wounds to the head and neck, including injuries to the esophagus, spinal cord, or cervical and cranial nerves, may damage vital respiratory or vascular structures. Subcutaneous emphysema, pneumomediastinum, esophagitis, esophageal strictures, and pneumothorax may develop. Pneumothorax is unlikely unless the parietal pleura are damaged. Damage to the thoracic cavity may cause a flail chest from broken ribs or intrathoracic hemorrhage or pneumothorax from vessel or airway damage. Continuous pleural suction may be needed to evacuate fluid or air in the chest cavity. Abdominal injuries can result in damaged or necrotic viscera. Exploratory celiotomy may be required after the animal has become stable enough for anesthesia. Complications of celiotomy include peritonitis, diaphragmatic hernia, or abdominal wall hernias. Neurologic injury may result if the axial skeleton or the peripheral nerves are damaged. Fractures and luxations require immediate consideration for decompressive and stabilization surgery, whereas nondisplaced structures should be managed conservatively. As with other compressive spinal cord injuries, pain sensation is the last to disappear and can be used as a prognostic indicator. Meningitis can be caused by penetrating injuries of the subarachnoid space and is more difficult to treat once it becomes established.

53.1.4.1.4

Wound Management

Wounds must be irrigated with copious quantities of isotonic saline, cleansing agents mixed with isotonic saline, or both. Soap and detergents have antiviral properties and have been shown to provide some local rabies virus prophylaxis. Antibiotic-containing solutions are not physiologic, are frequently irritating, and do not work well on direct contact for short periods (see [Table 53-4](#)). For lavage, diluted povidone-iodine solutions can serve as antimicrobials, but in the organic milieu of the wound they are less effective. Chlorhexidine has much better antibacterial activity in this regard and does not interfere with healing.

Any scabs, foreign bodies, or necrotic tissue should be removed during the initial debridement period. Necrotic muscle or fat should be removed cautiously to prevent damage to the remaining blood or nerve supply. Care should be taken to minimize the amount of tissue removed from viable tissue. Conservative removal allows for later evaluation (within 72 hours) to better determine demarcation of viable tissue.

Wounds that are already infected or have been present for longer than 24 hours should be treated as open wounds. Suturing bite wounds is generally not advocated unless the opening is approximated and drains are placed. Facial wounds with a rich blood supply are often closed to prevent scarring, as are extremity wounds that have less underlying tissue in which deep infections can hide. Such closures require close monitoring, and the animal should remain hospitalized or be checked daily.

Whether open or closed, wounds should be bandaged, elevated, and immobilized to prevent swelling and dehiscence. Collars or other restrictive devices are often needed to prevent animals from removing bandages and interfering with wound healing. For extremities, splinting and bandaging is the primary method of immobilization. Bandages protect tissue and absorb drainage from the open wound. Wet dressings may be applied if exudates are thick; however, moist bandages have the propensity to macerate tissue and allow for bacterial overgrowth. Antibiotic- or petrolatum-impregnated gauze prevents bacterial overgrowth or maceration of wounds; however, they may interfere with granulation tissue or epithelial growth within the wound. Contact layers of dressing should be nonadherent if the wound has minimal drainage and active granulation. Adherent and moistened contact layers are indicated if the wound has necrotic areas with viscous drainage. Adsorbent layers in moist dressings are soaked in antiseptic or saline

Infectious Diseases of the Dog and Cat, 3rd Edition

solutions and placed in the wound cavity before dressing with dry layers. For example, calcium alginate, a hydrophilic fiber, has been incorporated into wound dressings. Bandage material on the outer surface of open wounds should always be porous to allow ventilation of the lower layers. Moist bandages are changed several times daily; necrotic tissue is removed, and the wound is dressed and flushed with solutions before rewrapping. In later stages of wound healing, occlusive bandages are used to create a moist environment for granulation and epithelial growth. Hydrogels, hydrocolloids, or polyurethane foams are incorporated into bandages as nonadherent dressings in this phase.

Chemical restraint is often indicated for wound dressings and bandaging. Systemic narcotic analgesics may be used alone or in combination with sedatives or local anesthesia. Local anesthetics may interfere with epithelial growth and should be avoided in later stages of healing.

Drainage is an important component of wound management. Punctures or lacerations that caused injuries below the surface may have to be soaked daily with warm compresses and opened for drainage after seroma or abscess formation occurs. Healing may be by second intention. When dead space remains below the wound surface or drainage is excessive, a passive or an active drainage system must be instituted. Passive drainage relies on capillary action or gravity, whereas active drains rely on constant external suction. Drains should be removed when drainage becomes tenacious and exudative or septic.

Surgical closure of bite wounds is a controversial and complex subject beyond the scope of this chapter.

Surgical texts and other reviews should be consulted for a more extensive discussion.^{40,77} Primary closure is indicated early if tissues appear vital, infection or contamination is minimal, and dead space can be eliminated. Delayed primary or secondary closure may be indicated within 5 days after the wound occurs, when the wound is actively healing and has minimal exudation. The delay helps prevent scarring that develops from unapposed wound margins. Second-intention healing involves granulation, contraction, and epithelialization to close the entire wound and results in the most scarring; however, it must be used when excessive drainage, tissue loss, or infection within the wound exists.

53.1.4.1.5

Antimicrobial Therapy

Topical antimicrobial therapy is reserved for wound dressings on the outer skin surfaces. Empirical systemic antimicrobial therapy may be instituted to treat a broad spectrum of organisms, although antimicrobials alone have not been shown to prevent bite wound infections. Bite wounds are always contaminated with various environmental and commensal microflora. Antibiotics should be considered for wounds involving deep punctures or extensive surgical debridement. Animals that are immunocompromised because of various conditions, such as cats with retroviral infections or dogs with ehrlichiosis or infection with another persistent intracellular organism, may require more aggressive antimicrobial therapy. In general, intravenous therapy may be more effective than oral antibiotics in preventing infections associated with bite wounds. More rapid delivery of antibiotic in higher concentrations occurs with parenteral use.

Antibiotic selection should be broad so that it can be effective against most of the anticipated oral microflora of the dog and cat (Table 53-7). The most effective therapy is instituted within the first 3 hours of wounding. Few single agents can effectively treat the broad spectrum of organisms in the oral cavity. Amoxicillin-clavulanate has been the drug of choice during the contamination period, because it has a broad spectrum of efficacy and low toxicity. It acts against most of the organisms in the oral cavity of dogs and cats that can also be cultured from bite wounds.⁶⁷ Oral therapy is often used in conscious patients or for home treatment, although parenteral therapy often accompanies sedation or anesthesia for

507

508

Infectious Diseases of the Dog and Cat, 3rd Edition

wound management and is used to achieve more effective blood levels. Bacteria are often resistant to many penicillins without β -lactamase inhibitors and first-generation cephalosporins. Second-generation cephalosporins are not as effective as third-generation cephalosporins against anaerobes, although they are often preferred by veterinary surgeons. *Pasteurella* strains are commonly resistant to erythromycin, clindamycin, penicillin, and first-generation cephalosporins. Therefore when treating cat bite infections, these drugs should only be used in combination with other agents. For example, in severe and established wound infections, clindamycin can be combined with a fluoroquinolone or aminoglycoside to counteract a wide array of aerobic and anaerobic bacteria. Similarly, a first- and third-generation cephalosporin combination could be combined to create a similar broad-spectrum treatment. Drugs with an anaerobic spectrum of activity, such as metronidazole, must be given with other drugs that are effective against aerobic bacteria. Prophylactic therapy should continue for 3 to 5 days after infection is no longer apparent unless significant cellulitis is present; this may require longer treatment periods for management. If osteomyelitis is present, therapy often continues for a minimum of 6 weeks. Should the infection already be established at the time of first examination, therapy should also involve surgical drainage. A swab can be taken for culture, and additional material should be examined using a Gram stain to help the clinician choose more effective antibiotics. Therapy is often instituted before getting the results, and then the drug selection is modified based on the report.

Table 53-7 Recommended Therapy for Bite Infections

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL ^c (HOURS)	ANTIBACTERIAL SPECTRUM
Amoxicillin-clavulanate	D	10–20	PO	8	Most gram-positive and gram-negative aerobes and anaerobes; first-choice drug for most bite wounds
	D	13.75	PO	12	
	C	10–20	PO	12	
Ampicillin (amoxicillin)	B	22	PO	8	Some gram-positive and gram-negative aerobes
	B	11–22	SC, IV	6–8	
Ticarcillin	D	20–50	IV	6–8	Gram-positive and gram-negative aerobes and anaerobes
Cefotaxime	B	15–30	IV, IM, SC	6–8	Sepsis from bite wounds caused by gram-negative aerobes or anaerobes
Doxycycline	D	5	PO, IV	12	Some aerobes and anaerobes; mycoplasmas
Clindamycin	B	5–11	PO	8–12	Gram-positive aerobes and anaerobes
Enrofloxacin ^d	D	5	PO, SC	12–24	Gram-negative aerobes
Difloxacin ^d	D	5–10	PO	24	Gram-negative aerobes
Orbifloxacin ^d	D	2.5–7.5	PO	24	Gram-negative aerobes
Marbofloxacin ^d	D	2–4	PO	24	Gram-negative aerobes
Azithromycin	D	20	PO	24	Gram-positive aerobes; mycoplasmas and mycobacteria
Chloramphenicol	D	25–50	PO, IV, IM, SC	8	Some anaerobes; variable with gram-positive and gram-negative aerobes
Metronidazole	B	10	PO, IV	8	Anaerobes

D, Dog; C, cat; B, dog and cat; PO, by mouth; SC, subcutaneous; IV, intravenous; IM, intramuscular.

^a See [Appendix 8](#) for additional information on these drugs.

Infectious Diseases of the Dog and Cat, 3rd Edition

- b Dose per administration at specified interval.
- c Treatment should continue for 3–4 days after evidence of infection is no longer apparent.
- d See text for a list of appropriate combinations to achieve a broader spectrum. Use of only quinolones may predispose wound to necrotizing fasciitis from overgrowth of anaerobes and gram-positive bacteria.

53.1.4.2 Dog and Cat Bites in People

Judging from the discrepancy between the numbers of reported versus estimated bites, not all people who are bitten seek medical attention. In areas where it is required, bites should be reported to public health officials, whose job it is to investigate the incidents and make recommendations concerning the treatment of the person who was bitten and the disposition of the animal. Only a few states have developed formal guidelines for handling animal bites. Individuals who are immunocompromised and have been bitten or scratched should *always* be instructed to seek medical attention immediately. The need for prophylaxis for tetanus, rabies, or potential bacterial complications should be emphasized by medical professionals. 508
509

Although not primarily responsible for the treatment of bitten humans, veterinarians should be aware of the proper protocols for medical care (see Table 53-6). As in treating animal bites in dogs and cats, thorough washing of all bite wounds and scratches with soap and water is essential. Soaking in an aqueous organic iodine solution (1% povidone-iodine) may also be beneficial, but it may also irritate tissue and lead to secondary infection caused by contamination with bacteria such as *Pseudomonas* and may delay healing. Surgical scrubbing should not be performed because it is toxic to tissue. It is important that wounds be irrigated with physiologic solutions such as normal saline or lactated Ringer's solution. Intermittent, pulsating, high-pressure irrigation, which streams isotonic fluids directly into the wound, is most effective in dislodging contaminating bacteria. Irrigation is usually performed with an 18- to 20-gauge blunted needle or catheter, a 20- to 50-ml syringe, and approximately 150 ml of solution.⁹⁶

The degree of surgical intervention frequently depends on the site and type of bite. Facial injuries bleed profusely and produce highly visible scarring, so they are routinely sutured. Extremity wounds are less visible and often more contaminated and prone to infection, so they are often treated as open wounds. Puncture wounds with minimal hemorrhage should be irrigated, although some physicians cautiously excise the margins of the wound, leaving it open to drain. Unfortunately, this may create a larger, nonhealing wound. Any wound that becomes infected should be cultured. The affected extremity should be elevated to prevent swelling.

Whether antibiotics prevent infection after bite wounds is controversial. Antimicrobial therapy with penicillin or ampicillin-amoxicillin for 3 to 5 days has been recommended for all penetrating bite injuries, even though studies have questioned routine prophylaxis. This recommendation is based on the fact that most animal bite wound isolates, with the exception of staphylococci, are susceptible to penicillin G. Amoxicillin-clavulanate has also been recommended because of its broader and anaerobic spectrum.⁴⁹

Early initiation of antimicrobial prophylaxis can reduce the severity of infection, but the difference in overall numbers of infections that develop is not statistically significant when empirical prophylaxis is used. Therefore some question the need for routine treatment. When therapy is empirical, drugs with a gram-positive and anaerobic spectrum such as β -lactams are usually effective for this purpose. Therapy is generally used for 3 to 7 days for penetrating wounds. Amoxicillin-clavulanate has been a first-choice therapy; penicillin V is an alternative for less severe injuries. Increasing numbers of reports of β -lactamase–

Infectious Diseases of the Dog and Cat, 3rd Edition

producing strains of organisms such as *Capnocytophaga* species have warranted the use of the penicillins combined with inhibitors such as clavulanate. Doxycycline has been an alternative for patients who are allergic to penicillin. Generally, little need exists for culture of clinically uninfected bite wounds. Because of their polymicrobial nature, clinically infected bite wounds should be cultured. Resistant bacteria must be treated with cephalosporins or penicillinase-resistant antibiotics. Tetracycline is an alternative for patients who are allergic to β -lactam drugs. Use of erythromycin, clindamycin, first-generation cephalosporins, or dicloxacillin is often associated with microbial resistance, especially to *Pasteurella* spp. (For a discussion of therapy of wounds infected with rabies virus, anaerobic bacteria, or *Clostridium tetani*, see [Chapters 22, 41, and 43](#), respectively.)

53.1.4.2.1

Pasteurella Infections

Penicillin and its analogs such as ampicillin are the single most effective antibiotics for controlling *Pasteurella* infection in adults. Tetracyclines, chloramphenicol, trimethoprim-sulfonamides, quinolones, and second- and third-generation cephalosporins are similarly effective. Bacterial resistance to β -lactamase-resistant penicillins and to cephalosporins has been reported in 18% to 50% of animal isolates. Erythromycin does not control infection, and relapses can occur after its use is discontinued.

53.1.4.2.2

Capnocytophaga Infections

Many cases of *C. canimorsus* sepsis are fatal in people who are immunocompromised, although some people may completely recover even without antimicrobial therapy. Physicians and veterinarians should realize the potential risk that dog ownership creates for people who are immunocompromised and advise them to seek immediate medical care and antimicrobial treatment after bite injuries. Response to therapy in individuals treated early enough in the course of septicemia has generally been dramatic but not always curative. The organism shows in vitro susceptibility to many antimicrobials, including penicillin, ampicillin, amoxicillin-clavulanate, cephalosporins, tetracycline, carbenicillin, clindamycin, chloramphenicol, erythromycin, imipenem, and quinolone. *C. canimorsus* isolates have been resistant to the typical drugs, such as colistin, gentamicin, and kanamycin, selected to treat gram-negative infections. Susceptibility to trimethoprim-sulfamethoxazole has varied. Penicillin should be used as a first choice. In severely ill people a third-generation cephalosporin has been recommended to be given concurrently with penicillin because penicillin-resistant strains of *Capnocytophaga* and *Pasteurella* have been isolated on occasion.

53.1.4.2.3

Nonoxidizer-1 Infection

NO-1 bacteria are susceptible to various antibiotics. All strains have been susceptible to aminoglycosides, β -lactams, tetracyclines, quinolones, and sulfonamides.⁸⁴ At least 50% of the strains have been resistant to trimethoprim. β -Lactams should be the first choice for treating these infections.

53.1.5

Prevention

Avoiding actions that precipitate aggression in dogs and cats is key in preventing bite injuries (see [Table 53-2](#)). Pet owners can avoid selecting breeds or breed mixes with known aggressive tendencies. Male, unneutered, free-roaming dogs of German shepherd, pit bull, or chow chow breeding seem to present the greatest risk. Neutering aggressive male dogs is advised. Early experiences and socialization, including proper handling and attention during the neonatal period, are essential for puppies and kittens. Veterinarians should advise clients

Infectious Diseases of the Dog and Cat, 3rd Edition

with children to obtain a young dog so that it can be more easily socialized in the new environment. They can educate families who want to acquire new animals about the known relative risks associated with particular dog breeds. During initial training, dogs should be taught not to sleep on furniture or eat or beg at meals and that the people in the household are in charge. Children should be educated about proper behavior around dogs. They should avoid running or screaming in the presence of dogs. They should not reach outward with their hand to greet unknown dogs or hug them as they would another person. Children should always allow a dog to sniff them before they pet the animal. People with a higher risk for bites because of their occupations, such as animal control officers, postal employees, meter readers, and animal health workers, should be provided education programs to help them interpret canine and feline communicative behaviors. Crown reduction, an endodontic method for disarming the canine teeth, has been used to reduce the injury caused by biting dogs and cats¹⁴⁷ but is probably not very effective in preventing injuries from dog bites.^{133,169}

53.2 RAT BITE INFECTIONS

Two commensal organisms of rodents are responsible for a bacterial disease that develops in dogs, cats, and people who have direct or indirect contact with rodent tissues or their secretions. *Streptobacillus moniliformis* is a small (0.25 to 0.5 μm \times 1 to 3 μm), motile, aerobic, pleomorphic gram-negative bacillus with unipolar flagella. *Spirillum minus* is a motile, gram-negative spiral organism (3 to 5 μm) that has polar flagellar bundles.

These species of bacteria are resident nasopharyngeal flora in up to 50% of wild or laboratory rodents. Subclinical infections of rats with *S. moniliformis* are prevalent worldwide, although some rats have abscess formation and develop a purulent infection. Other rodents such as mice and guinea pigs more commonly develop clinical illness when infected. The prevalence of infection with *S. minus* in rats is more variable and depends on the geographic location, although most are inapparently infected.

Dogs and cats contaminate their oral cavities with these bacteria while catching rodents. They can also harbor the agents subclinically and act as mechanical vectors because they can transmit their recently acquired infection to people by biting.¹²⁵ Occasionally, abscesses develop in dogs or cats, presumably as a result of a rat bite.

Infected people have fever, myalgia, arthralgia, lymphadenitis, and generalized exanthematous eruptions that may develop weeks or months after bites.¹⁶ Epidemic infections have rarely been reported after laboratory or foodborne contamination. Endocarditis and polyarthrititis are chronic sequelae. With infections caused by *S. moniliformis*, the site of the original bite usually heals by the time clinical signs are seen. With infections caused by *S. minus*, the healed wound may become reinfamed and later ulcerate during the course of febrile illness. Regional lymphadenitis and lymphangitis are common in the region of the bite.

S. moniliformis can be isolated in culture on serum-enriched media, and a diagnosis requires notifying the laboratory that the organism may be involved. Isolation from blood must not be made in blood culture media because the typical anticoagulant—polyanethol sulfonate—inhibits the organism's growth. *S. moniliformis* has the propensity to convert to pleomorphic, cell-wall-deficient, L forms in vivo or in vitro, during unfavorable growth conditions, or during β -lactam therapy (see L-Form Infections, [Chapter 32](#)). *S. minus* does not grow on laboratory media, so dark-field examination of exudates or inoculation of mice with blood from affected patients is necessary to confirm the infection.

Penicillin is the drug of choice for infection caused by either organism. Tetracyclines are indicated for animals with resistant or L-form infections (see [Table 32-2](#) and [Appendix 8](#) for dosages). Oral infections of dogs and cats are usually inapparent, so treatment is unnecessary. In animals with abscess formation, surgical drainage should accompany anti-microbial therapy.

Bartonella is a fastidious genus of hemotropic bacteria, the members of which have each become highly adapted to preferential mammalian reservoir hosts and within which the adapted bacterial species usually causes a long-lasting intraerythrocytic bacteremia.^{115,131} *Bartonella* spp. are vector transmitted, and the vector preference for particular host species has resulted in the evolution of individual sylvatic transmission cycles. In the natural reservoir host, chronic bacteremia with a *Bartonella* spp. can frequently be detected by culture or polymerase chain reaction (PCR) testing in seemingly clinically healthy individuals. Until recently, mechanisms that facilitate persistent *Bartonella* bacteremia in mammals were not well understood. However, the intraerythrocytic localization for these bacteria is a unique strategy for bacterial persistence.* Nonhemolytic intracellular colonization of erythrocytes would preserve the organisms for efficient vector transmission, protect *Bartonella* from the host immune response, and potentially contribute to decreased antimicrobial efficacy.¹⁹⁵

511

Species of *Bartonella* are small, curved, gram-negative bacteria and include organisms that once comprised the genera of *Bartonella*, *Rochalimaea*, and *Grahamella* (Fig. 54-1 and Table 54-1).^{17,30,212} *B. bacilliformis*, the original type species, causes a focally occurring vasculoproliferative and hemolytic disease of people in the Andes Mountains of Peru. *B.* (formerly *Rochalimaea*) *quintana*, the cause of trench fever in World War I, also causes bacillary angiomatosis, endocarditis, and chronic lymphadenomegaly, predominantly in immunocompromised people.^{58,70,127,130} *B. quintana* is transmitted by the body louse and has also been detected in cat fleas in France¹⁹⁷; however, this potentially incidental finding may relate to recent feeding on an infected host. *B. (Rochalimaea)* *henselae*, a feline-adapted *Bartonella* species, has usually been isolated from clinically healthy cats, although some strains of the organism have been associated with relatively mild illnesses and histopathologic lesions. In contrast, people with *B. henselae* infections have developed bacillary angiomatosis, visceral bacillary peliosis (extravasation of blood), relapsing fever with bacteremia, meningitis, encephalitis, neuroretinitis, endocarditis, and pyogranulomatous lymphadenitis (cat-scratch disease [CSD]).^{128,187,193,215} *B. henselae* was detected using PCR testing in the liver of a dog with peliosis hepatis,¹²⁶ the liver of a dog with granulomatous hepatitis,⁸⁵ and blood of three dogs with other serious illness or immunosuppression.[†] Closely related to *B. henselae*, *B. clarridgeiae* comprises approximately 10% to 30% of *Bartonella* isolates from clinically healthy cats[‡] and was found in endocarditis lesions in one dog⁵² and in another dog with hepatopathy using PCR testing⁸⁵ (see Canine Bartonellosis later). *B. clarridgeiae* has been serologically associated with CSD-like illness in people.^{135,147,20,105} *B. koehlerae*⁷¹ was isolated from two healthy cats and a human with endocarditis^{4a}; and *B. bovis* (formerly *B. weissii*)^{15,188} was isolated from four cats; the pathogenic significance of these two species in cats has not been determined. *B. (Rochalimaea)* *elizabethae* was isolated from a human immunodeficiency virus infected person with endocarditis.⁶² PCR testing in blood of a moribund dog with renal failure and anemia.¹⁶⁶ *B. (Rochalimaea)* *vinsonii* subsp. *vinsonii* has only been isolated from voles. *B. vinsonii* subsp. *berkhoffii* has been isolated from the blood of healthy and diseased dogs, healthy coyotes, and from one human being with endocarditis.^{39,137,202} *B. vinsonii* subsp. *arupensis* was isolated from a cattle rancher with fever and bacteremia.²³⁰ Species from the former genus *Grahamella*, *B. talpae*, and *B. peromysci*, and three new species, *B. grahamii*, *B. taylorii*, and *B. doshiae* isolated from small feral mammals, were unified in the genus *Bartonella*.¹⁷ *B. grahamii* was associated with neuroretinitis in one person.¹²³ Additional species or subspecies, isolated from woodland mammals and for which the pathogenic potential in cats, dogs, or people has yet to be defined, include *B. alsatica*, *B. birtlesii*, *B. capreoli*, *B. schoenbuchii*, *B. tribocorum*, and *B. chomeli*.[§] The possibility exists that new *Bartonella* pathogens and disease manifestations will be observed in the future. With respect to feline and canine infections, the following discussion of *Bartonella* in animals focuses on

Infectious Diseases of the Dog and Cat, 3rd Edition

B. henselae, *B. clarridgeiae*, and *B. vinsonii* subsp. *berkhoffii*. These and other species of *Bartonella* infecting people and their zoonotic implications are discussed under Public Health Considerations.

54.1 FELINE BARTONELLOSIS

Lynn Guptill-Yoran

54.1.1 Epidemiology

Since the first recognition of feline *B. henselae* infection in 1992,¹⁹⁰ it has been established that cats may be naturally infected with four *Bartonella* species: *B. henselae*, *B. clarridgeiae*, *B. koehlerae*, and *B. bovis*.^{*} Serologic and blood culture data indicate that exposure to *Bartonella* spp., most frequently *B. henselae*, is prevalent among cats in the United States and throughout most temperate regions of the world. Domestic and wild cats throughout North America, Eastern and Western Europe, Africa, Australia, and Southeast Asia have been found to be infected with *Bartonella* species.¹⁶⁹ Prevalence in domestic cats is lowest in Northern Europe and the Rocky Mountain regions of the United States and Canada, and greatest in warmer, more humid regions (Fig. 54-2). There are two main genotypes of *B. henselae*. The Houston 1 genotype is more prevalent in the Far East, and the genotype Marseille is predominant in western Europe, Australia, and the western United States.

Infectious Diseases of the Dog and Cat, 3rd Edition

Both genotypes are equally prevalent in the eastern United States. ^{49a} A third genotype, designated Berlin, was indentified in a cat from Germany. ⁴ Seroepidemiologic studies in cats generally show a higher prevalence of seroreactivity with age, warmer temperature, and higher humidity, and in feral cats and those infested with fleas. [†] <i>B. henselae</i> bacteremia affects approximately 5% to 40% of cats in the United States, depending on geographic location and is most common in temperate areas. [‡] Prevalence rates of <i>B. clarridgeiae</i> infections were reported to be approximately 10% in cats with <i>Bartonella</i> bacteremia evaluated in the United States, 16% to 31% of cats with <i>Bartonella</i> bacteremia in France, and 31% of cats in the Philippines that had <i>Bartonella</i> bacteremia. ^{48,105,136} <i>B. koehlerae</i> was isolated from two cats (from the same household in California), and <i>B. bovis</i> was isolated from two cats in Utah and two in Illinois. ^{71,188} Domestic cats are considered the major reservoir and vector for human infections with <i>B. henselae</i> and for <i>B. clarridgeiae</i> . Cattle are the reservoir for <i>B. bovis</i> . The reservoir for <i>B. koehlerae</i> is unknown. In France, molecular methods detected <i>B. quintana</i> , <i>B. koehlerae</i> , <i>B. henselae</i> , and <i>B. clarridgeiae</i> in cat fleas, along with rickettsial pathogens. ¹⁹⁷ This finding suggests that fleas may be involved in the transmission of many of these bartonellae for people and animals; however, the fleas had just fed on their host. Additional evidence that arthropods serve both as reservoirs and vectors of some <i>Bartonella</i> species comes from finding these organisms in questing ticks. ^{36,169b} Biting flies have also been infected with <i>Bartonella</i> . ^{55a}	511 512 512 513

(Map data from references 116 and 149; inset courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Wild felids are also exposed to *Bartonella* spp.; 18% of panthers in Florida and 28% of mountain lions in Texas had serum antibodies to *B. henselae*, and the prevalence of serum antibodies to *B. henselae* in free-ranging and captive wild felids in California was 30% to 53%.^{201,240} Prevalence of serum antibodies to *B. henselae* in pumas (*Felis puma concolor*) and bobcats (*Lynx rufus*) in Mexico, Central America, and South America ranged from 0% to 33%.⁵¹ *Bartonella* infection has also been documented in free-ranging wild and captive African lions (*Panthera leo*) and cheetahs (*Acinonyx jubatus*), using serology, PCR testing, and blood culture.^{169,49a}

B. henselae contains multiple genetically diverse strains. Two recognized 16S rRNA types of *B. henselae* (Houston 1 [type I] and Marseille [type II]) and at least two subgroups are within each type.^{157,242} Cats can be co-infected with *B. henselae* 16S rRNA types I and II and co-infected with *B. henselae* and *B. clarridgeiae*.¹⁰⁰ In cats, co-infection also exists with hemotropic *Mycoplasma* spp. that cause erythrocytic mycoplasmosis (haemobartonellosis), given that they are also transmitted by cat fleas (see [Chapter 31](#)).¹⁴⁵ Regional differences in prevalence of infection of cats exist with different rRNA types of *B. henselae*.^{13,93,101,105} Some evidence is suggestive of genomic variation in *B. henselae* during the course of infection in cats.¹¹⁹ Such variation may enhance the ability of *B. henselae* to persist in an infected cat for prolonged periods. Whether the 16S rRNA type is the most accurate means of describing genetic differences among *B. henselae* isolates has not yet been determined. Multiple other methods are under investigation, and the full extent of genetic diversity within *B. henselae*, is yet to be defined.^{68,113,114,141} Genetic variation makes vaccine development difficult (see Pathogenesis) but is useful in epidemiologic studies and may also be useful in furthering the understanding of the pathogenicity of various *Bartonella* isolates.

54.1.2 Pathogenesis

B. henselae is believed to be naturally transmitted among cats by cat fleas (*Ctenocephalides felis felis*). The exact role of the flea in transmission has not been determined. *B. henselae* was transmitted among cats by transferring fleas fed on infected cats to specific-pathogen-free (SPF) cats, and by intradermal (ID) inoculation of flea excrement.^{49,78} Cats exposed to *Bartonella*-infected fleas that were confined to capsules that permitted fleas to feed, but prevented contamination of cats' skin and hair coat with flea excrement, did not become infected with *B. henselae*.⁷⁸ This finding suggests that transmission does not occur via flea saliva. Ticks may have a role in transmission; *B. henselae* and other *Bartonella* spp. were detected by PCR test in questing ticks in California,^{36,38} and from *Ixodes ricinus* ticks in Italy.²⁰⁸ Ticks have been proposed as the vectors for transmission of some *Bartonella* infections in people, dogs, and other mammalian hosts.^{11,183,215,230}

Cats were experimentally infected with *B. henselae* through intravenous (IV) or intramuscular (IM) inoculation with infected cat blood,¹³⁴ and by IV, subcutaneous, ID, or oral (PO) routes of inoculation with plate-grown

Infectious Diseases of the Dog and Cat, 3rd Edition

bacteria.^{1,91,92,177} *B. henselae* transmission has not occurred when infected cats cohabit with uninfected cats in a flea-free environment,^{1,92} indicating that transmission among cats does not occur through cat bites, scratches, grooming, or sharing of food dishes and litter boxes. Transmission did not occur when cats were inoculated IM with urine of bacteremic cats.¹³² Transmission also did not occur between bacteremic female cats and males during mating, or to the kittens of infected females either during gestation or in the neonatal period,^{1,96} again in flea-free environments.

Bacteremia with *B. henselae* and *B. clarridgeiae* is commonly chronic and waxes and wanes; periods occur when bacteremia cannot be detected either by culture or by PCR testing. Measured increases in IL-4 and serum antibody titers in response to the peak of bacteremia subsequently decrease the bacteremia to low or undetectable levels.^{119a} Experimentally infected cats maintained *B. henselae* or *B. clarridgeiae* bacteremia for as long as 454 days.¹³⁴ Naturally infected cats maintained recurrent bacteremia for periods of as long as 3 years; however, reinfection via fleas of cats living in private homes may occur.¹³⁸

Immune mechanisms are important in the suppression or elimination of infection in cats. Complete protection against reinfection is highly specific, even with strains of a given species of *Bartonella* and likely in reactivity to the outer membranes of the organism.⁴¹ A lack of protection against reinfection has been demonstrated in cats previously infected with *Bartonella*. Cats previously infected with *B. henselae* 16S rRNA type II were susceptible to infection with *B. henselae* 16S rRNA type I.²³⁷ Cats infected with *B. henselae* type I or II were susceptible to challenge infection with *B. clarridgeiae*, and cats infected with *B. koehlerae* or *B. clarridgeiae* were susceptible to challenge infection with *B. henselae* type I or type II.²³⁹ In contrast, cats infected with *B. henselae* type I were partially or completely protected against challenge infection with *B. henselae* type II.²³⁹ The level of bacteremia and degree of susceptibility to reinfection following challenge inoculation is likely to vary with strains, as well as with species, of *Bartonella*.²³⁷

513

514

Despite the lack of protection against heterologous challenge, cats can become immune to ID challenge with homologous strains of the organism.^{89,237} Cats can still be reinfected with the same strain through blood transfusions.^{89,132} These findings suggest that the intracellular localization of the organism provides protection from immune clearance mechanisms.

The extent of localization of *Bartonella* in cats has not been completely determined. *Bartonella* are intracellular bacteria. *B. henselae* have been detected within erythrocytes of naturally infected cats^{198,210,211} and in vitro (Fig. 54-3).¹⁶⁴ *Bartonella* may also be located intracellularly in vascular endothelial cells of infected cats as has been suggested for rodents (Fig. 54-4, A and B).⁶⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

54.1.3 Clinical Findings

Few cats naturally infected with *Bartonella* have clinical signs (Table 54-2). Four cats developed fever following elective surgical procedures.²¹ One cat with uveitis had a serologically positive result for *B. henselae*¹⁴⁴ and 7 of 49 cats with uveitis (14%) had evidence of ocular production of anti-*Bartonella* immunoglobulin G (IgG) antibodies by higher than expected levels in aqueous humor relative to those in sera.¹⁴⁶ Whether members of the genus *Bartonella* contribute to previously described instances of argyrophilic bacteria in lymph nodes of cats with persistent lymphadenomegaly¹²⁵ or to peliosis hepatis in cats³² is unknown.

Clinical signs in experimentally infected cats are usually mild and transient; therefore naturally infected cats may have clinical signs that owners do not observe. Severity of clinical signs in cats experimentally infected with *B. henselae* varied with the strain of *B. henselae* used for inoculation.^{95,134,177} Cats inoculated ID developed areas of induration or abscess at inoculation sites between 2 days and 3 to 4 weeks after inoculation* from some of which pure cultures of *B. henselae* were obtained⁹⁵ (Fig. 54-5). Other transient clinical findings included generalized or localized peripheral lymphadenomegaly (lasting for approximately 6 weeks following inoculation), short periods of fever (over 39.4° C [103° F]) during the first 48 to 96 hours following inoculation and again at approximately 2 weeks following inoculation, mild neurologic signs (nystagmus, whole body tremors, focal motor seizures, either decreased or exaggerated responses to external stimuli, behavior changes), and epaxial muscle pain. Some cats are lethargic and anorexic during febrile periods.[†] Reproductive failure occurred in some cats experimentally infected with *B. henselae*.⁹⁶ Cats experimentally infected with *B. koehlerae* exhibited no clinical signs.²³⁸

B. henselae type I was associated with fatal blood culture-negative vegetative aortic valve endocarditis in two cats.^{53,49a} *B. henselae* DNA was detected in the aortic valve. Occasional silver-stained coccoid structures were seen in endothelial cells of the myocardium, but no bacteria were seen on transmission electron microscopy of the aortic valve.

- a Most consistently seen with experimental infections and signs vary according to the tested strain. *B. koehlerae* has not been tested.
- b Sample obtained from to a commercial diagnostic laboratory where health status of the cat was unknown.
- c *Bartonella* infection in these retrospective studies was diagnosed by serologic fluorescent antibody testing.
- d *Bartonella* infection in these studies was diagnosed by serologic enzyme-linked immunosorbent assay.
- e Serologic testing was performed with an immunoblotting procedure.

A potential causative role of *Bartonella* spp. in chronic diseases of cats has been proposed because *Bartonella* bacteremia is prolonged. A Japanese study suggests that co-infection of cats with *B. henselae* and feline immunodeficiency virus was more likely to cause gingivitis or lymphadenomegaly than was either infection alone.²²⁴ Results of a Swiss study suggest possible associations between *B. henselae* seropositivity and stomatitis and various urinary tract disorders.⁸⁶ Both studies obtained serum and historical information about cat health from practicing veterinarians. Plexiform vascularization of the lymph nodes, which has been described as a clinical entity in cats,²³² resembles visceral peliosis of people that is associated with *B. henselae* infections. Further studies are needed on this and other conditions (see Table 54-2) to determine whether they are associated with *B. henselae* infections in cats.

Fig 54-5 Postinoculation papule 20 days after ID inoculation of *B. henselae* in a cat. The size of the papule increased from the time of inoculation and only *B. henselae* was isolated from bacterial culture of an aspirate. Bar = 1 cm. (Courtesy Lynn Guptill, Purdue University, West Lafayette, Ind.)

Infectious Diseases of the Dog and Cat, 3rd Edition

A contribution of *Bartonella* infections to development of chronic illnesses in domestic cats has not been verified. For example, suggestions indicate that infected cats have a greater prevalence of chronic gingivitis, stomatitis, or ocular lesions, but this is not proven.^{103a-b} No significant differences were found in the prevalence rate for PCR or serum antibody-positive results between cats with stomatitis and age-matched control cats.^{69a} Because of the high prevalence of *Bartonella* infection in the domestic cat population, proof of a causative association between any disease or syndrome and *Bartonella* infection will require extensive, carefully controlled epidemiologic investigations.

* References: 90, 95, 134, 168, 177.

† References: 95, 132, 134, 168, 177.

54.1.4 Diagnosis

As a result of the transient and protean nature of clinical signs, determining which cats are likely to have *Bartonella* infection is difficult. In addition to the need to test for *Bartonella* infections in sick cats, veterinarians will be asked to test healthy pet cats belonging to clients with *Bartonella*-related illnesses or to screen healthy cats that are being considered as pets for people considered most susceptible to *Bartonella* infections (see Public Health Considerations).

54.1.4.1 Clinical Laboratory Findings

Most experimentally infected cats had no abnormalities on complete blood counts, serum biochemical tests, or urinalysis. Some cats had transient anemia early in the course of infection, and some had persistent eosinophilia.¹³⁴ Mature neutrophilia occurred in some cats during periods of skin inflammation.⁹⁵

54.1.4.2 Cytologic Detection

Finding *B. henselae* in erythrocytes of infected cats has not been an effective means of detection using conventional staining methods. Special confocal microscopy (see Fig. 54-3) and staining has been used.²¹⁰ Intraerythrocytic location of *B. clarridgeiae* and *B. koehlerae* have also been documented in cats using fluorescent antibody (FA) detection methods.^{197,199} In addition, extracellular *B. henselae* have been documented in peripheral blood and other tissues of infected cats using immunocytochemical and immunohistochemical methods.⁹⁸

54.1.4.3 Bacterial Isolation

A positive blood culture result or culture of other tissue is the *most reliable test for definitive diagnosis* of active *Bartonella* infection. However, because of the relapsing nature of feline *Bartonella* bacteremia, culture is not always a sensitive diagnostic tool. Blood culture is indicated for sick cats whose history and clinical presentation suggest possible *Bartonella* infection or when a client's physician requires such testing of pet cats. Blood for culture should be obtained using sterile technique, and the blood placed in ethylenediaminetetra-acetic acid (EDTA)-containing tubes or lysis centrifugation blood culture tubes (Isolator tubes, Wampole, Cranbury, N.J.). If blood is collected into EDTA tubes, the blood should be chilled or frozen during shipment; ideally, plastic EDTA tubes should be used. Blood should be sent to laboratories familiar with the culture of these fastidious organisms (see Appendix 5). Laboratories should be contacted

Infectious Diseases of the Dog and Cat, 3rd Edition

for specific instructions for sample collection and submission. Blood culture is not recommended for absolute screening of cats because of potential false-negative results during lapses in bacteremia. Initial screening to eliminate any potential for infection is probably best done using serology, which overestimates the number of infected cats.

54.1.4.4 Serologic Testing

Measuring serum antibodies has limited value for determining whether an ill cat has an active *Bartonella* infection but is useful for epidemiologic surveys and can be useful for screening. Serum IgG antibodies persist in experimentally infected cats for prolonged periods. How long antibodies persist following clearance of infection is not known. Indirect FA, enzyme immunoassay (EIA), and Western blot tests are available. Because of the genetic diversity of *Bartonella* organisms, infections with some strains or species of *Bartonella* may be missed using any method, depending on the antigen preparations used.⁸⁴ The positive predictive value of indirect FA or EIA (IgG) serologic tests for bacteremia is only 39% to 46%. The utility of a negative serologic result is greater because the negative predictive value for these tests for bacteremia is high at 89% to 97%.^{12,45,93,101} Nevertheless, some seronegative bacteremic cats exist.^{55,93,185} A positive correlation may exist between indirect FA titer and level of bacteremia²³⁹; however, cut-off values allowing use of serologic testing to determine whether a cat is currently infected with *Bartonella* have not been established.

54.1.4.5 Immunoblotting

The use of Western blot tests has been advocated for serodiagnosis of feline *B. henselae* infections, but the diagnostic accuracy of Western blot tests awaits further investigation. In human medicine, variability in Western blot testing remains problematic. Serologic responses of people as evaluated by immunoblot vary from patient to patient.²⁰⁵ Results of studies of Western blot analyses of cats infected with *B. henselae* have differing results. Results of one study indicated no differences in Western blot patterns of cats evaluated over the course of infection when sera from multiple time points were incubated with polyacrylamide gel-separated proteins of bacterial isolates from multiple time points in infection.¹³⁴ Results of another study indicated that antibodies in sera of infected cats reacted with an increasing number of bands of polyacrylamide gel-separated proteins over the course of infection.^{81,93}

54.1.4.6 Nucleic Acid Detection

Standard PCR testing for the presence of *Bartonella* DNA is often no more sensitive than blood culture is for detecting active *Bartonella* infection, and detecting DNA does not always equate to detection of living organisms. Using PCR, *B. henselae* DNA has been detected in the dental pulp of 1-year-old and 800-year-old cat cadavers.^{1a,141a} Extraction methods from blood are extremely critical in determining the sensitivity of PCR test and can be responsible for false-negative results when compared with blood culture.^{89,176} Nested PCR testing may increase sensitivity for detection of *Bartonella* DNA in cat blood²⁰⁴ and may be available through some research laboratories (see [Appendix 5](#)). A benefit of PCR testing is that the product obtained in the reaction may be sequenced and the species or strain (or both) of *Bartonella* therefore identified. In addition, the results of PCR testing are often available more quickly than are those of blood culture. PCR methods have been described that allow for rapid differentiation of pathogenic *Bartonella* spp.^{117,221} Blood samples for PCR testing should be obtained using the same sterile technique recommended for blood culture.

Infectious Diseases of the Dog and Cat, 3rd Edition

Care must be taken in collection and sample processing to avoid sample contamination and DNA degradation. Contact individual laboratories for submission guidelines (see [Appendix 5](#)).

54.1.5 Pathologic Findings

Acutely and chronically infected cats had hyperplasia of lymphoid organs, small foci of lymphocytic, pyogranulomatous, or neutrophilic inflammation in multiple tissues (lung, liver, spleen, kidney, heart) ([Figs. 54-6](#) and [54-7](#))—or necrotic foci associated with pyogranulomatous inflammation—usually in liver or lymphoid tissues ([Fig. 54-8](#)).^{95,134}

54.1.6 Therapy

Documentation of clearance of *Bartonella* infections through antibiotic treatment is difficult because of the prolonged relapsing bacteremia of infected cats. No regimen of antibiotic treatment has been proven effective, in controlled studies with long-term follow-up, for definitively eliminating *Bartonella* infections in cats.^{11,90,136,192} Enrofloxacin (5.4 to 7.6 mg/kg, given PO, every 12 hours) for 14 or 28 days appeared to clear *B. henselae* or *B. clarridgeiae* infection in 4 of 6 or 5 of 7 treated cats, respectively, that were followed for 12 weeks after treatment.¹³⁶ However, studies show that enrofloxacin causes retinal degeneration in cats, and use of doses of greater than 2.5 mg/kg, given every 12 hours, is contraindicated.²³⁴ Doxycycline (4 to 12 mg/kg, given PO, every 12 hours) cleared bacteremia in only one of six cats treated for 14 days and one of two cats treated for 28 days.¹³⁶ Antibiotics tested in other studies, including erythromycin, amoxicillin, amoxicillin-clavulanate, and tetracycline, rapidly decreased the level of bacteremia in infected cats. However, in one study, treated and untreated cats became blood-culture negative after the same period, making proof of efficacy of antibiotics difficult. In another study, cats were not followed for more than 8 weeks after treatment, thereby making it difficult to assess drug efficacy resulting from the possibility of chronic relapsing bacteremia in these cats.^{90,192} In experimental infections, the effective doxycycline dose in cats has been a minimum of 10 mg/kg twice daily,⁸⁸ which is similar to that recommended in treating infections with other related persistent intracellular organisms such as *Brucella canis* and *Ehrlichia canis* in dogs. In experimental studies in cats, rifampin alone and in combination with doxycycline has been effective in clearing *B. henselae* bacteremia.⁸⁸ Azithromycin has been recommended for treatment of infected cats, but data from controlled efficacy studies with long-term follow-up are lacking. Azithromycin was used to treat seropositive cats with uveitis^{103b,124}; however, documentation of infection by detection of organisms was lacking. Similarly, azithromycin has been used to treat seropositive cats with gingivitis and stomatitis and other inflammatory conditions.^{103a} Despite clinical improvement in some cats, no proof has been found that the serologic titer results indicate exposure to this or oral microorganisms responsible for the inflammation. Azithromycin appears to have important immunomodulatory and antiinflammatory properties in addition to the broad antimicrobial spectrum of this antibiotic.^{61,142,143,178} These properties may make it difficult to determine whether beneficial effects reported following azithromycin treatment of cats are solely a result of anti-*Bartonella* activity or instead are a result of azithromycin's other properties, of the antimicrobial action of azithromycin on other bacteria, or of a combination of all of these.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 54-3 Suggested Antibiotic Dosage for Bartonellosis Infections of Cats^a

Drug ^b	DOSE ^c (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION ^d (WEEKS)
Enrofloxacin ^e	5 mg/kg	PO	24	2–4
Doxycycline	10–22 mg/kg ^f	PO	12	2–4
Rifampin ^g	10 mg/kg	PO	24	2
Azithromycin	10 mg/kg	PO	24	1 ^h

- a Data from references 136, 89, 90, and 124. Efficacy of these drugs in clearing bacteremic cats is controversial.
- b For further information on these drugs, see Drug Formulary, [Appendix 8](#).
- c Dose per administration at specified interval.
- d Giving these drugs for 4 weeks appears to be more efficacious than for 2 weeks.
- e Doses greater than 5 mg/kg/day have been associated with retinal degeneration in cats, but 5 mg/kg may be ineffective.
- f The dose should be rounded up to give whole tablets or capsules to avoid esophageal irritation.
- g Rifampin is effective alone or in combination with doxycycline but has to be reformulated so that the dose given here can be administered. Rifampin should ideally be given in combination with another drug in treatment-resistant cases to reduce the possibility of inducing antibacterial resistance in *Bartonella* that might eventually pose a public health risk.
- h After the first week, the same dose is given every other day for 5 weeks.

Fig 54-8 Necrotizing granuloma in the lymph node of a cat infected with *B. henselae*, 56 days following inoculation (H and E stain, ×200). (Reprinted from Guptill et al. 1997. Experimental infection of young specific pathogen-free cats with *Bartonella henselae*, *J Infect Dis* 176:206–216. Used with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Recommended dosages are listed in [Table 54-3](#). However, because of the uncertainty of antibiotic efficacy, several followup blood cultures should be performed at 4- to 8-week intervals *after* discontinuation of antibiotic treatment.^{90,136,192} Because routine treatment with antibiotics may induce resistant strains, recommendations are to treat only cats showing clinical signs or when euthanasia is the only alternative to treatment.¹³⁶ Although treatment decreases the level of bacteremia in cats, no concrete evidence has been found that treatment of the cat will decrease the probability of transmission of *Bartonella* infection to an owner. Client education regarding the uncertainty of treatment efficacy and the need for prolonged followup is important. The importance of flea control and other means of preventing transmission (see Prevention) should be emphasized.

People with *Bartonella* infections causing bacillary angiomatosis or peliosis or endocarditis are treated with a variety of antibiotics, including doxycycline, erythro-mycin, ciprofloxacin, rifampin, gentamicin, trimethoprim-sulfamethoxazole, clarithromycin, and azithromycin.^{9,155} Azithromycin was shown in a controlled clinical trial to have some efficacy for decreasing lymph node size in people with CSD.⁹

54.1.7 Prevention

Prevention of *Bartonella* infections in cats is best accomplished by avoiding exposure to infected animals and their fleas. Because *B. henselae* and *B. clarridgeiae* have been transmitted through inoculation of infected cat blood,¹³² cats should not receive blood transfusions from cats of unknown *Bartonella* status or cats that are seropositive for *Bartonella*. A vaccine to prevent *Bartonella* infection in cats is not available. If a vaccine were developed, it would by necessity have to protect against a wide variety of strains.

54.1.8 Public Health Considerations

People are susceptible to infection with at least nine *Bartonella* species or subspecies, including *B. quintana*, *B. bacilliformis*, *B. henselae*, *B. clarridgeiae*, *B. vinsonii* subsp. *berkhoffii*, *B. vinsonii* subsp. *arupensis*, *B. grahamii*, *B. elizabethae*, and *B. washoensis*, the latter seven of which are considered zoonotic. Cats are the reservoir and vector for transmission of *B. henselae* and possibly (but uncommonly) *B. clarridgeiae* to people. Coyotes are probably a reservoir for *B. vinsonii* subsp. *berkhoffii*. Rodents are likely reservoirs for other zoonotic *Bartonella* spp. The role of fleas, ticks, and other arthropods in direct transmission of any of these species of *Bartonella* to people is not certain. Transmission of *B. henselae* from cats to people is believed to occur through contamination of cat scratches with flea excrement.⁴⁹ Transmission may also occur through cat bites if cat blood or flea excrement contaminates the bite site.^{232a}

Bartonella spp. cause a wide variety of clinical syndromes in people, including CSD (typical and atypical forms, including encephalopathies in children); bacillary angiomatosis and peliosis; parenchymal bacillary peliosis; relapsing fever with bacteremia; endocarditis; optic neuritis; pulmonary, hepatic, and splenic granulomas; and osteomyelitis.* Immunocompetent individuals usually have more localized infections ([Fig. 54-9](#)), whereas infections in immunocompromised individuals are more often systemic and can be fatal. Diagnosis in people is usually made by serologic testing or PCR testing because of the low level or absence of bacteremia in immunocompetent hosts. In one study, a high prevalence of antibodies to *B. henselae* was found among children in Italy, without evidence of obvious illness.¹⁶¹ This finding suggests that exposure and nonsymptomatic infection occurred during exposure early in life with spontaneous resolution. Evidence suggests that certain genotypes of *Bartonella* may induce different pathologic features in infected people.^{35,235} For example, only rRNA type I isolates were associated with hepatosplenic peliosis. Close typing of isolates

Infectious Diseases of the Dog and Cat, 3rd Edition

from people and their cats' contacts show them to be related, thus incriminating the cats as the source of human infection. Clients should be informed of the current understanding of how dogs and cats acquire *Bartonella* infections and how these infections may be transmitted to people, including the possibility of transmission by ticks or fleas.

Fig 54-9 Enlarged lymph nodes in a person with CSD. (Courtesy University of Georgia, Athens, Ga.)

Common sense precautions for avoiding transmission of *Bartonella* spp. from pets to people include ongoing flea and tick control, avoiding interactions with cats and dogs that result in scratches or bites, thoroughly washing bite or scratch wounds, and acquiring new pets of known good health status that are and have been ectoparasite free. Stray or impounded cats less than 1 year are most likely to be infected. No evidence has been found that declawing cats decreases the probability of transmission of *B. henselae* between cats and human beings. The United States Public Health Service/Infectious Diseases Society of America (USPHS/IDSA)

*Guidelines for Preventing Opportunistic Infections Among HIV-Infected Persons*²²⁶ recommends the following when acquiring a new cat: adopt a cat older than 1 year of age that is in good health, avoid rough play with cats, maintain flea control, wash any cat-associated wounds promptly, and do not allow a cat to lick wounds or cuts. The USPHS/IDSA Guidelines note that no evidence has been found to indicate any benefit to cats or their owners from routine culture or serologic testing of cats for *Bartonella* infections.

54.2 CANINE BARTONELLOSIS

Edward B. Breitschwerdt

Infectious Diseases of the Dog and Cat, 3rd Edition

Bruno B. Chomel

54.2.1 Epidemiology

B. vinsonii subsp. *berkhoffii* was isolated from a dog with endocarditis in our laboratory in 1993.^{27,137} Retrospectively, long-term administration of immunosuppressive doses of glucocorticoids for a presumptive diagnosis of systemic lupus erythematosus may have facilitated the isolation of the original type strain of *B. vinsonii* subsp. *berkhoffii* from this dog with endocarditis. Because of the relatively recent recognition that dogs can be infected with *B. vinsonii* subsp. *berkhoffii* and potentially other *Bartonella* spp., seroprevalence data is limited.^{6,109,111,183} Seroprevalence was determined in 1920 sick dogs from North Carolina or surrounding states that were evaluated at a veterinary teaching hospital.¹⁸³ Using a titer of over 1:32, only 3.6% of sick dogs had antibodies to *B. vinsonii* subsp. *berkhoffii*. Risk factors, expressed as odds ratio (OR), that may be associated with seroreactivity included heavy tick exposure (OR 14.2), cattle exposure (OR 9.3), rural versus urban environment (OR 7.1), and heavy flea exposure (OR 5.6). These data were interpreted to support the possibility that exposure to *B. vinsonii* subsp. *berkhoffii* was more likely in dogs in rural environments that were allowed to roam. In addition, these dogs were likely to have a history of heavy tick infestation. Using sera from dogs experimentally infected with *Rickettsia rickettsii* or *Ehrlichia canis*, cross-reactivity to *Bartonella* antigens was not detected. However, 36% of serum samples derived from dogs naturally infected with *E. canis* were reactive to *B. vinsonii* antigens. Because *E. canis* is transmitted by *Rhipicephalus sanguineus*, this tick may be involved in the transmission of *B. vinsonii*. The possibility of tick transmission was further supported by two additional studies involving dogs infected with one or more *Ehrlichia* spp. from the same geographic region, in which seroreactivity to *B. vinsonii* subsp. *berkhoffii* antigens was 30% and 89%, respectively.^{25,139} Seroprevalence, using *B. vinsonii* subsp. *berkhoffii* antigens, was 10% (4 out of 40 dogs) in those with suspected tick-borne illness from Israel and 36% in dogs with fever and thrombocytopenia from Thailand.^{6,220} Using an enzyme-linked immunosorbent assay, 35% of 869 samples, derived from coyotes (*Canis latrans*) in California, contained antibodies to *B. vinsonii* subsp. *berkhoffii* antigens.⁴⁰ The organism has been isolated from wild coyotes incriminating them as a likely wildlife reservoir in the western United States.³⁹ Dogs with *Bartonella*-induced endocarditis in California also had positive antibody titers to *Anaplasma phagocytophilum*, suggesting common tick vector exposure.¹⁵¹ In the southeastern United States, epidemiologic evidence suggests that *Amblyomma americanum* or *Dermacentor* may be involved in transmission because co-infections with other tickborne organisms carried by these ticks have been documented.^{25,139,183} Current data indicates that exposure to *B. vinsonii* subsp. *berkhoffii* can be found throughout much of the United States and most tropical and subtropical regions of the world. The organism has been identified in *Ixodes* with PCR methods.^{119a}

54.2.1.1 Other Bartonellae

Based on cultural and molecular evidence, *B. vinsonii* subsp. *berkhoffii* is considered the most frequent *Bartonella* species that causes disease in dogs. However, this conclusion may not be accurate because sera from dogs have not been screened systematically against a large panel of *Bartonella* spp. antigens, and minimal PCR testing has been performed. Studies from Hawaii, the United Kingdom, and Japan identified *B. henselae* seroprevalence of 6.5% (2 of 31 dogs), 3.0% (3 of 100 dogs) and 7.7% (4 of 52 dogs), respectively.^{8,67,222} Although the pathogenicity of all *Bartonella* spp. in dogs is poorly characterized, it is becoming increasingly clear that species other than *B. vinsonii* subsp. *berkhoffii* can infect dogs.^{122,140,222} For example, *B. henselae* was amplified and sequenced on two independent occasions from the liver of a dog

Infectious Diseases of the Dog and Cat, 3rd Edition

with peliosis hepatis.¹²⁶ This is a unique pathologic lesion that is induced only by *B. henselae* infection in people.¹¹⁵ Recently, *B. henselae* DNA was amplified from a dog with granulomatous hepatitis, a histopathologic lesion that is reported with some frequency in children infected with *B. henselae*.⁸⁵ Similarly, *B. clarridgeae* DNA has been amplified and sequenced from the liver of a Doberman pincher with copper storage disease and from the aortic valve of a dog with vegetative valvular endocarditis.^{52,85} *B. elizabethae*, a species for which rodents are the reservoir, was PCR amplified and sequenced from an EDTA blood sample obtained from a dog that had experienced chronic weight loss culminating in sudden unexplained death.¹⁶⁶ *B. henselae*-specific antibodies were detected in the sera of healthy (10.8 %) and sick (28.5%) dogs from North Carolina²¹⁷ and in 14% of clinically healthy dogs that were tested.^{119a} Many of the dogs showed seroreactivity to other vector-borne diseases, indicating the potential for combined infections. Cross-reactivity to infection with other closely related *Bartonella* cannot be eliminated in some animals. These observations indicate that, although presumably infrequent, the *Bartonella* spp. that frequently infect cats or rodents and are transmitted by fleas among reservoir hosts may cause disease manifestations in dogs. Genetic methods have been used to substantiate many of the *Bartonella* infections in dogs, inasmuch as they are presumably unnatural hosts and levels of organisms are low and difficult to cultivate. *Bartonella* is closely related to members of the α -*Proteobacteria*, and bacteria in this group or other as yet unclassified members of the genus *Bartonella* may also be important as causes of infection in dogs.²²

54.2.2 Pathogenesis

Although as yet unproven, *B. vinsonii* subsp. *berkhoffii* is presumably transmitted to dogs by the bite of an infected tick. If similar to other *Bartonella* spp., the organism causes chronic intraerythrocytic and endothelial cell infections and is presumably well tolerated by the dog for extended periods. Similar to other highly adapted intracellular vector-transmitted pathogens, the factors that ultimately result in these organisms causing disease manifestations are yet to be determined. If similar to babesiosis, another intraerythrocytic pathogen, stress, hard work, parturition, or concurrent infection with other organisms may contribute to the development of pathology. Following experimental inoculation of SPF dogs with culture grown *B. vinsonii* subsp. *berkhoffii*, sustained suppression of peripheral blood CD8+ lymphocytes was noted accompanied by an altered cell surface phenotype and an increase in CD4+ lymphocytes in the peripheral lymph nodes.^{179,181} Therefore infection with *B. vinsonii* subsp. *berkhoffii* might induce a degree of chronic immunosuppression that may predispose dogs to secondary infections, resulting in a wide array of clinical manifestations in naturally infected dogs.

The extent to which infection with *Bartonella* influences the pathophysiology of ehrlichiosis, a disease of much longer historical venue, deserves critical reappraisal. For example, infection with *Bartonella* in dogs concurrently infected with *E. canis* may contribute to the tendency to develop epistaxis (see [Chapter 28](#)). Of similar potential concern in both canine and human medicine is the finding of co-segregation of *Borrelia burgdorferi* ([Chapter 45](#)), *Anaplasma phagocytophilum* (previously *Ehrlichia equi* or human granulocytic ehrlichiosis, [Chapter 28](#)), *Babesia microti* ([Chapter 77](#)), and *Bartonella vinsonii* (*arupensis*) in *I. scapularis* ticks in the northeastern and north-central United States. Regional differences in tick species, accompanied by differences in the bacterial, viral, and protozoal organisms that ticks transmit, create substantial challenges for the clinician in regard to diagnosis and medical management. From an evolutionary perspective, it is obvious that vectors, vector-borne organisms, and animal and human hosts have developed a highly adapted form of mutual interaction. In general, vectors need blood for nutrition; the bacterial, rickettsial, and protozoal organisms need an intracellular environment to survive; and immunologically, most hosts appear able to support chronic infection with many vector-borne organisms for months to years without obvious deleterious

Infectious Diseases of the Dog and Cat, 3rd Edition

effects. These factors serve to illustrate the potential difficulty in establishing causation in dogs or people co-infected with individual or multiple tick-transmitted pathogens.

519

520

54.2.3 Clinical Findings

54.2.3.1 *B. vinsonii* subsp. *berkhoffii*

The spectrum of disease associated with *Bartonella* infection in dogs and most other animal species is continuing to expand (Table 54-4). Endocarditis associated with *B. vinsonii* subsp. *berkhoffii* occurs in large breed dogs with a potential predisposition for aortic valve involvement.^{22,27,52} Boxer dogs have been especially prevalent in this syndrome. In some dogs, intermittent lameness, bone pain, or fever of unknown origin can precede the diagnosis of endocarditis for several months, whereas other dogs will show an acute history of cardiopulmonary decompensation (Fig. 54-10). Cardiac arrhythmias secondary to myocarditis can be detected in dogs without echocardiographic evidence of endocarditis. Leukocytosis, thrombocytopenia, hypoalbuminemia, azotemia, and proteinuria with a clean sediment are found in a majority of affected dogs.^{23,151}

Bartonella-induced granulomatous lymphadenitis, involving the left submandibular lymph node, was diagnosed in a dog based on seroreactivity to *B. vinsonii* subsp. *berkhoffii* antigens, visualization of Warthin-Starry silver-staining bacteria within the lymph node (Fig. 54-11), and PCR amplification followed by Southern blot hybridization.¹⁸⁰ Seven days before enlargement of the lymph node, the owners removed an engorged tick from the left ear. This case provides the best evidence to date that ticks can transmit *Bartonella* spp. to dogs and potentially to people. The granulomatous lymphadenitis in this dog is analogous to acute bartonellosis CSD in people, in which a scratch or bite injects the inoculum (usually *B. henselae*), rather than inoculation by the bite, of a tick.¹¹⁵ Based on serologic evidence in dogs, *B. vinsonii* subsp. *berkhoffii* or closely related *Bartonella* spp. appear to contribute to the development of dermatologic lesions indicative of a cutaneous vasculitis, anterior uveitis, polyarthritis, rhinitis, meningoencephalitis, or immune-mediated hemolytic anemia.²³ Anterior uveitis and choroiditis were observed in one dog.¹⁶⁷

Co-Infections

As with other tickborne illnesses, infections from multiple agents can occur simultaneously. This finding may cause confusion because of additional unexplained clinical signs that do not resolve with therapy.

520

Babesia canis and *B. vinsonii* subsp. *berkhoffii* infection occurred in a dog and resolution of signs only occurred after both infections were treated.²²³

54.2.3.3 Other Bartonellae

A dog with peliosis hepatis caused by *B. henselae* developed generalized weakness and abdominal distention. Biochemical abnormalities were high serum alkaline phosphatase (ALP) activity, hyponatremia, and hypochloremia. A serosanguineous abdominal effusion was found as were multiple fluid-filled cysts in the liver.¹²⁶ Another dog with chronic hepatitis, where *B. henselae* DNA was detected, had fever, anorexia, weight loss, icterus, and increased serum ALP and alanine aminotransferase activities.⁸⁵

B. elizabethae DNA was amplified and sequenced from the blood of a dog with chronic weight loss and sudden unexplained death presumably from cardiac dysfunction.¹⁶⁶ *B. clarridgeiae* DNA was amplified and sequenced from the aortic valve of a dog with vegetative valvular endocarditis and manifestations of third-degree heart block, causing heart failure.⁵² *B. clarridgeiae* DNA was found in the liver of a Doberman pinscher with hepatic copper storage disease that had high hepatic enzyme activities on a routine preanesthetic blood testing.⁸⁵

B. washoensis was isolated from a dog with a heart murmur and congestive heart failure caused by vegetative endocarditis.

Infectious Diseases of the Dog and Cat, 3rd Edition

54.2.4 Diagnosis

54.2.4.1 Clinical Laboratory Findings

Thrombocytopenia, anemia, which frequently can be immune mediated, and neutrophilic leukocytosis are the most commonly detected hematologic abnormalities in dogs that are seroreactive to *B. vinsonii* subsp. *berkhoffii* antigens. Thrombocytopenia is found in approximately one half of the dogs with disease manifestations. Eosinophilia is also found in approximately one third of infected dogs. Monocytosis can also occur in *B. vinsonii*-infected dogs, particularly those with endocarditis. Hemoglobinuria, generally unaccompanied by hematuria, is a frequent finding, particularly in dogs with immune-mediated hemolytic anemia. Serum biochemical abnormalities are usually very mild or nonexistent. Antinuclear antibodies have been detected in dog sera that were reactive to *B. vinsonii* subsp. *berkhoffii*, *E. canis*, and *Leishmania infantum* antigens.²¹⁶ These titers may represent cross-reactive antinuclear antibodies that are induced by exposure to bacterial DNA which has analogous sequences of the mammalian host.

54.2.4.2 Radiographic Imaging

Dogs infected with *B. henselae* may have hypoechoic cystic lesions in parenchymal organs (Fig. 54-12). In *B. vinsonii* subsp. *berkhoffii* infections, valvular endocarditis leads to cardiac failure, with the left side most commonly involved. Pulmonary edema will develop in cases of advanced insufficiency (see Fig 54-10). Echocardiographic changes are valvular vegetations and regurgitant flow can be observed with color-flow Doppler studies (Fig. 54-13, A and B).

54.2.4.3 Bacterial Isolation or Detection

Attempts to isolate *B. vinsonii* or other *Bartonella* from immunocompetent dogs with serologic or molecular evidence of *Bartonella* infection have not been successful in most instances. When using the currently recommended microbiologic techniques, considerable variation appears to exist in the degree of difficulty associated with the isolation of different *Bartonella* spp. from the blood of different animal species. Because blood culture is insensitive, serology and PCR amplification of *Bartonella* DNA are the mainstays of diagnosis. Because seroprevalence to *B. vinsonii* subsp. *berkhoffii* antigens is infrequently detected (under 4%) in sick dog populations in endemic regions, detection of antibodies in a sick dog provides strong clinical evidence for prior exposure and potentially active infection. For this reason, treatment of seroreactive dogs or dogs from which *Bartonella* spp. DNA is detected in blood or tissue samples would be recommended. A titer of 1:64 or greater is considered indicative of prior exposure to or active infection with *B. vinsonii* subsp. *berkhoffii*. Given that isolation of *Bartonella* from dogs is usually unsuccessful, PCR testing on blood or tissues is the best method of detecting species other than *B. vinsonii* subsp. *berkhoffii*. Because more recent evidence indicates that *B. henselae* may contribute to the development of disease manifestations, such as polyarthritis and hepatitis, serologic testing for *B. henselae* antibodies has been validated using canine sera. In the southeastern United States, *B. henselae* seroprevalence is approximately 10% in healthy dogs and 26% in sick dogs.^{217,218} This finding indicates that exposure to *B. henselae* is much more frequent than exposure to *B. vinsonii* subsp. *berkhoffii* is in dogs in the southeastern United States. Therefore, until additional research is completed, canine seroreactivity to *B. henselae* antigens should be interpreted with caution.

Fig 54-12 Ultrasonographic appearance of the liver of a dog with peliosis hepatis, associated with *B. henselae* infection showing hypoechoic areas (arrows) representing vascular peliosis. (Courtesy Barbara Kitchell, University of Illinois, Urbana, Ill.)

Serologic and molecular evidence indicates that co-infection in dogs with *Ehrlichia*, *Babesia*, *Rickettsia*, and *Bartonella* spp. may be more frequent than previously realized.* Because certain *Borrelia*, *Ehrlichia*, *Babesia*, and *Bartonella* spp. can cause chronic, insidious infection in dogs, the relative role of each organism to the pathogenesis of specific disease manifestations in a sick, naturally infected dog will remain difficult to establish in the clinical setting. When dealing with sick dogs with a history of tick exposure, clinicians should screen by serologic or molecular testing modalities for a panel of tick-transmitted pathogens.

* References: 22, 25, 27, 139, 183, 220.

54.2.5 Pathologic Findings

In dogs, pathologic findings associated with *Bartonella* spp. infections include endocarditis (Fig. 54-14), myocarditis, granulomatous lymphadenitis or hepatitis, and peliosis hepatis (Fig. 54-15). Multifocal areas of severe myocardial inflammation can be found in dogs with *B. vinsonii* endocarditis. Although not specific for *Bartonella* infections, organisms can be detected in acutely diseased tissues, such as acute regional lymphadenitis, using silver stains (see Fig. 54-11). During chronic infections, organisms are presumably too few in number to be detected in tissues by silver staining, unless localized to heart valves.

521

54.2.6 Therapy

To date, an optimal protocol has not been established for the treatment of *Bartonella* infections in cats, dogs, or people.^{162,200} Regardless of the antibiotic that is used for treatment, a long duration of antibiotic administration (4 to 6 weeks) may be necessary to eliminate the infection (Table 54-5). Macrolides (erythromycin, azithromycin) most probably represent the oral antibiotic class of choice for treating *Bartonella*

522

infections.^{162,200} Fluoroquinolones alone or in combination with amoxicillin have also elicited a positive

523

therapeutic response in dogs, which is accompanied by a progressive decrease in *B. vinsonii* antibody titers.²³ Doxycycline may be effective for treatment of *B. vinsonii* subsp. *berkhoffii*, but data from cats experimentally or naturally infected with *B. henselae* or *B. clarridgeae* indicates that a high dose (10 mg/kg every 12 hours) for 4 to 6 weeks may be necessary to eliminate *Bartonella* infection in dogs, cats, or other animal species. *B. vinsonii* subsp. *berkhoffii* has been cultured from the blood of dogs that were treated with doxycycline for weeks to months for ehrlichiosis.²⁰ Following effective antimicrobial therapy, apparently, *Bartonella* serum antibody titers decrease rapidly (3 to 6 months) and are generally no longer detectable in dogs that recover completely following antimicrobial therapy. Persistence of *Bartonella* antibodies may be indicative of treatment failure. Therefore posttreatment serology may be a useful adjunct to determine therapeutic elimination of *Bartonella* infections. Dogs with *B. vinsonii* subsp. *berkhoffii* infection often have large valvular vegetative lesions by the time a diagnosis is made. Antibiotic penetration is difficult in these lesions, and signs of heart failure eventually

Infectious Diseases of the Dog and Cat, 3rd Edition

occur. Surgical valve replacement is often used to treat people with this condition; however, it is not being done in animals.

Table 54-5 Suggested Antibiotic Dosage for Bartonellosis Infections of Dogs^a

DRUG ^b	DOSE ^c (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Doxycycline	10–15	PO	12	4–6
Enrofloxacin	5	PO	12	4–6
Azithromycin ^d	5–10	PO	24	6
PO, By mouth.				

- a Efficacy of these drugs to treat dogs with these infections is poor, especially with endocardial lesions.
- b See Drug Formulary, [Appendix 8](#), for additional information on these drugs listed below.
- c Dose per administration at specified interval.
- d Azithromycin is given every 24 hours for the first week then every 48 hours for the next 5 weeks.

Fig 54-16 Abscess in the spleen from a dog ([Fig. 54-13, A and B](#)) with endocarditis from *B. vinsonii* subsp. *berkhoffii*. (Courtesy University of Georgia, Athens, Ga.)

54.2.7 Prevention

Increasingly, veterinarians play an important role in advising the public as to the epidemiologic and zoonotic implications associated with vector-borne pathogens. Nondomestic animals frequently serve as the primary reservoir for *Bartonella* spp. For example, the coyote appears to be an important reservoir host for *B. vinsonii* subsp. *berkhoffii*.³⁹ Although somewhat circumstantial, increasing evidence suggests that *Bartonella* spp. can

Infectious Diseases of the Dog and Cat, 3rd Edition

be transmitted by fleas and ticks to cats, dogs, and people.^{22,36,183} Based on scientific evidence generated during the last several decades, vector-transmitted pathogens can induce clinical manifestations ranging from acute fatal illness (e.g., Rocky Mountain spotted fever, ehrlichiosis, babesiosis, bartonellosis) to chronic debilitating disease states (ehrlichiosis, babesiosis, borreliosis, and bartonellosis). Therefore minimizing or eliminating flea and tick exposure is perhaps of greater veterinary and public health importance today than during any previous time in history. When rigorous flea and tick control measures are instituted, it is highly probable that transmission of *Bartonella* spp. will be greatly reduced or eliminated.¹³³

54.2.8 Public Health Considerations

B. vinsonii subsp. *berkhoffii* was isolated from a human endocarditis patient.²⁰² The extent to which dogs can serve as a reservoir host for *B. vinsonii* subsp. *berkhoffii* or other *Bartonella* spp., such as *B. henselae*, *B. clarridgeae*, or *B. elizabethae*, is poorly characterized. Although dogs have been implicated in the direct transmission of *B. henselae* to people by a scratch or bite, this mode of transmission is as yet poorly established.

55 CHAPTER 55 Surgical and Traumatic Wound Infections

Craig E. Greene

Michael G. Dearmin

Virtually every surgical wound becomes contaminated, but only a few become infected. Bacterial infections have hindered successful healing of operative wounds throughout the history of surgery. The use of aseptic methods and minimization of tissue trauma were major breakthroughs in reducing postoperative infections. Subsequent development and use of antibiotics in surgery further reduced numbers of surgical infections. The prevalence of nosocomial infections is increasing again because of the more invasive and prolonged surgical procedures, synthetic implants being used today, and drug-resistant bacteria.

55.1 ETIOLOGY

The skin serves as a barrier to contamination but is compromised by surgical incisions, so the resulting wound must progress through the predictable stages of wound healing. As mentioned, contamination of the wound bed occurs with every surgical procedure, but most surgical wounds do not develop an infection. The success of wound healing is influenced by the overall health of the patient, the surgical procedure and type of wound created, and the type and number of contaminating organisms introduced into the wound.

The major source of bacteria contaminating surgical wounds is the patient's endogenous microflora. Skin-associated bacteria can be reduced but not eliminated by disinfection. Bacteria residing in the deeper parts of the skin such as the hair follicles and sebaceous glands are not removed or killed by preparative scrubbing, and they may enter deeper tissues during the initial incision. Nosocomial infections can also arise from inadequate sterilization of surgical equipment, operating room air flow, or the veterinary staff or hospital environment. Microbes indigenous to the hospital environment are most problematic because they are often antimicrobial resistant. A National Research Council (NRC) wound classification system of human surgical wound contamination can be applied to veterinary practice and is summarized in [Table 55-1](#). In a study of 1574 dogs and cats with clean, clean contaminated, contaminated, or dirty surgical wounds, infection rates were 4.7%, 5%, 12%, and 10%, respectively.⁶ Anaerobic bacteria should always be assumed to be a component of mixed surgical infections,¹³ or numerous therapeutic failures could result.

Clean surgical wounds involve surgical incision sites with no prior trauma or inflammation, no breaks in sterile technique during surgery, and mucosal surfaces such as the respiratory, genitourinary, or alimentary tracts that are not compromised. Infection rates in animals with clean surgical wounds are very low when experienced surgeons perform the procedures and in some reports have been as low as 0.9%.³² *Clean contaminated surgical wounds* involve minor breaks in surgical technique (such as a torn glove), contact with normal mucosae of the gastrointestinal (GI) tract without spillage of visceral contents, or contact with uninfected genitourinary, biliary, or respiratory tracts. They also include otherwise clean procedures involving drain placement. Infection rates in people for these surgical procedures are less than 10% when aseptic techniques are used.³¹ Oral antimicrobial prophylaxis may be needed for upper alimentary surgery when antacids have been used preoperatively to decrease gastric acidity, possibly causing gastric bacterial flora to proliferate. *Contaminated surgical wounds* have accidental GI tract spillage from penetration of an infected viscus or tissue, foreign bodies, devitalized tissue, or pus or involve a break in sterile technique. Bacterial contamination is suspected, but purulent discharge is absent. Clean lacerations of the skin or subcutaneous tissues that are not already infected are often categorized as

Infectious Diseases of the Dog and Cat, 3rd Edition

contaminated. Contaminated surgical wounds have a high risk for developing postoperative infections and are two times more likely to become infected than clean contaminated wounds.³¹ For example, after colonic spillage, isolated pathogens are often mixed, and up to five species may be present. Aerobic species usually include *Escherichia coli* and enterococci, and anaerobes include *Bacteroides* species, anaerobic cocci, and clostridia (see [Chapter 89](#), Intraabdominal Infections).²⁹ *Infected (dirty) surgical or traumatic wound infections* are surgical wounds or nonsurgical defects that are already infected or have breaks in the skin associated with blunt trauma. Devitalized tissues, foreign bodies, or purulent discharges are often observed. Examples of dirty wounds include previously perforated viscera, devitalized wounds, compound fractures, foreign bodies, pus pockets, and acute cellulitis. Traumatic wounds are assumed to be contaminated and have a high risk of infection because microbes bypass the anatomic and immunologic barriers of the host. Necrotizing soft tissue infections are almost always colonized by numerous anaerobic and aerobic bacteria.¹⁴ Bacteria from these wounds have often already spread systemically. Establishment of tissue infection depends on the type and depth of the injury, extent of damage to the vascular supply, extent of tissue devitalization, and length of delay in seeking treatment. With orthopedic injuries, posttraumatic osteomyelitis occurs when a broken bone has a contaminated open wound, an avascular fragment, and a milieu of damaged necrotic tissue or hemorrhage⁵ (see Musculoskeletal Infections, [Chapter 86](#)). Subsequent to trauma and hospitalization, urinary and IV catheter infections are the most common infections, followed by pneumonia, intraabdominal infections, and wound infections. Responsible organisms are often staphylococci, *E. coli*, *Enterobacter*, *Pseudomonas*, and *Klebsiella*. (See [Chapter 53](#) and reviews by Holt and Griffin²⁰ and Underman⁴⁰ for a discussion of bite wound infections; see [Chapter 35](#) for a discussion of necrotizing fasciitis; see [Chapter 94](#) for a thorough discussion of surgical preparations needed to prevent postoperative infections.)³²

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 55-1 Classification of Surgical Wounds and Indications for Prophylaxis^a

CLEAN	CONTAMINATED
1. Wound from elective surgery	1. Fresh traumatic wound
2. Nontraumatic	2. Break in sterile technique
3. No entry into mucosal surface	3. Spillage from GI surface
4. No break in asepsis	4. Acute inflammation
5. No inflammation or drainage encountered	5. Dental prophylaxis ^b
6. 2.5% ^c –4.7% ^d infection rate	6. Mucosal surgery
	7.5.8% ^c –12% ^d infection rate
CLEAN CONTAMINATED	INFECTED (DIRTY)
1. Bacterial entry into GI, genitourinary, or respiratory tract mucosae with minimal spillage or simple laceration	1. Abscessed material present
2. No unusual contamination, no suppurative inflammation	2. Viscus perforated or fecal contamination
3. Minor break in asepsis	3. Older (>4-hr) traumatic wound
4. 4.5% ^c –5% ^d infection rate	4. Suppuration
	5. Major break in asepsis
	6.18.1% ^c –10% ^d infection rate

- c Prevalence of wound infections in dogs and cats from a veterinary teaching hospital.⁶
- d Prevalence of wound infections in dogs and cats from a veterinary teaching hospital.⁶

The NRC wound classification system has been widely used since its development in 1964. However, the risk for development of infection depends on many factors other than the wound environment. In an attempt to account for such other factors in estimating the risk of wound infection, the National Nosocomial Infections Surveillance System (NNISS) developed an index to predict risk of surgical infection.¹⁰ A risk index score of 0, 1, 2, or 3 is based on the sum of three risk factors: (1) an American Society of Anesthesiologists preoperative assessment score of 3, 4, or 5 ([Table 55-2](#)); (2) an operation with an NRC classification of *contaminated* or *dirty*, and (3) an operative time of *X* hours, where *X* represents the time in which 75% of the given surgical procedures are completed. When the index was developed, it was compared with the NRC classification of surgical wound infections from more than 80,000 surgical procedures. Surgical wound infection rates for the NRC classification system were 2.1%, 3.3%, 6.4%, and 7.1% for each respective category. The NNISS index surgical wound infection rates were 1.5% with zero risk factors present, 2.9% with one risk factor present, 6.8% with two risk factors present, and 13% with three risk factors present. Compared with the NRC classification, risk stratification was significantly increased with the NNISS index. Such an index may not be practical in many veterinary

Infectious Diseases of the Dog and Cat, 3rd Edition

situations; however, the results of this comparison highlight the need to consider factors other than simply the wound type when evaluating infection risk.

Table 55-2 American Society of Anesthesiologists: Preoperative Assessment Scores
--

I.	Healthy, no organic disease
II.	Local disease with no systemic signs
III.	Disease causing moderate systemic signs that limit function
IV.	Disease causing severe systemic signs that threaten life
V.	Moribund; not expected to live 24 hours with or without surgery

Modified from Owens WD, 1978. Physical status classification: a study on consistency of ratings, *Anesthesiology* 49:239–243.

The process of wound healing should be viewed as a complex interaction between the patient, the local wound environment, and the contaminating pathogen. Each facet of this interaction has many associated factors, the combination of which are unique to each situation. A thorough assessment of these factors and the common sources of perioperative contamination ([Table 55-3](#)) should be considered when preparing for each surgical procedure so that the most appropriate steps can be taken to minimize the risk for the development of postoperative infection ([Table 55-4](#)).

Hematogenous to implants

Preoperative preparation of the surgical site is a critical factor in preventing wound infection (see [Chapter 94](#)). Skin trauma produced during surgical preparation greatly increases the local bacterial population. Preoperative clip-ping time is an important factor in the development of postoperative wound infections.⁶ Animals with surgical sites that were clipped before anesthesia induction rather than immediately before surgery were 3 times more likely to develop surgical wound infections. Animals clipped hours or days before the surgery because ultrasonographic studies were performed had a postoperative infection rate 3 times greater.⁶ Animals with endocrinopathies such as hypothyroidism or hyperadrenocorticism are much more likely to develop postoperative wound infections.²⁸ Intact males were also found to have a higher risk of wound infection, which parallels findings in people and rodents and is presumably a result of the inhibitory effect of testosterone on some inflammatory cytokines.³⁶

Use of proper surgical technique is perhaps the single most important factor in preventing postoperative infections. The risk of tissue infection is directly proportional to the increased amount of tissue handling and trauma. Vascular compromise to tissue, excessive electrocautery, and bleeding into tissue spaces are the major contributory factors. Foreign material and blood clots allow for adherence and replication of microorganisms. Experimentally, use of fibrinolytic agents prevents infections, abscesses, and adhesions after surgery. Bacteria that invade surgical sites or implants can remain dormant for months to years and although less common, the sites can be entered during the healing and recovery phases. In some animals, occult orthopedic infections develop. The bacteria remain at the site of the healed fracture but do not cause clinical or radiographic evidence of osteomyelitis.¹² The infection may persist locally until the orthopedic implants are removed. Surgical wounds may be colonized with *Staphylococcus aureus*, a human commensal flora, which may lead to infections that are resistant to treatment if methicillin-resistant staphylococci are involved.³⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 55-4 Methods for Reducing Risk of Surgical Wound Infection
--

PREOPERATIVE

Minimize length of preoperative hospitalization.

Treat with antimicrobial or do not perform surgery on animals with concurrent infections.

Treat remote sites of infection before operating.

Widely clip hair around incision site.

Shave skin just before surgery.

Prepare skin with povidone-iodine or chlorhexidine.

INTRAOPERATIVE

Use prophylactic antimicrobials when (1) manipulating contaminated tissues or intestine, (2) for prolonged surgical procedures (>3 hr), and (3) with synthetic implants.

Keep surgical room free of dust and insects.

Keep surgical field clean, and use routine antiseptic technique.

Ensure that incision and dissection are accurate and sharp.

Avoid excessive use of electrocautery.

Prevent normal skin or mucosal flora from contacting body cavities or internal tissues.

Minimize drying and exposure of handled tissues.

Surgically debride all tissues to healthy vascular areas.

Remove all foreign bodies, avascular tissue, and dead space.

Irrigate contaminated areas with antimicrobial or disinfectant solutions.

Infectious Diseases of the Dog and Cat, 3rd Edition

Avoid circulatory compromise.

Use meticulous hemostasis to decrease risk of tissue hemorrhage and blood clots (hematoma formation).

Place stab wounds drains at other than incision sites.

Delay surgical closure with dead space.

Handle soft tissues and abdominal viscera gently.

Change suction tips during prolonged surgical procedures.

Reduce number of people in the operating room.

POSTOPERATIVE

Delay closure of contaminated wounds.

Change intravenous catheters routinely.

Prevent aspiration pneumonia.

Keep drainage established, and irrigate healing wounds.

Orthopedic implants have greatly improved treatment of bone fractures and noninfectious arthritis, but they are associated with an increased risk for orthopedic-device-related infection.⁴⁷ Immediately after implantation, all synthetic materials undergo a race in colonization of their surface by tissue and bacterial cells in the local area. In addition to body fluids containing serum proteins (albumin) and platelets, bacteria such as staphylococci have adhesins that attach bacteria to the biomaterial. Adherence leads to colonization of the foreign body surface, which can result in overt infection or bacteremia. Under these conditions, bacteria become sessile and develop antimicrobial resistance in this quiescent phase. Standard antimicrobial therapy at this time may eliminate the clinical illness, but the bacteria may persist in the biofilm. Various organisms such as coagulase-negative staphylococci and *Pseudomonas aeruginosa* produce a pathogenic biofilm composed of polysaccharide glycocalix (slime). With strict anaerobic conditions or with molecular identification techniques, anaerobes such as *Propionibacterium* species are often recognized.³⁹ They form an additional layer on the surface of prosthetic implants that can originate during the surgical procedure.² The glycocalix slime promotes intercellular adhesion, captures nutrients, and protects microorganisms from antibacterial therapy.

526

527

The use and timing of prophylactic antimicrobial therapy affects infection rates in animals with clean surgical wounds. In a study at a teaching hospital, 72.5% of 1100 animals with clean surgical wounds received perioperative antibiotics, which was associated with a lower infection rate.⁴² However, in another comparable study in which 41% of 1146 animals with clean surgical wound received antibiotics at varying times, the infection

Infectious Diseases of the Dog and Cat, 3rd Edition

rate varied according to the timing of the antibiotic administration.⁶ Animals with clean wounds receiving perioperative antibiotics, no antibiotics, or postoperative antibiotics had infection rates of 2.2%, 4.4%, and 8.2%, respectively. In another study at a teaching hospital, dogs undergoing elective orthopedic surgery were divided into three groups and given either no antimicrobials, penicillin G, or cefazolin 30 minutes before surgery, and again if the surgery lasted longer than 90 minutes.⁴⁶ Dogs in both antibacterial treatment groups had lower infection rates, therefore the control group was abandoned. Results in these studies emphasize the importance of having maximal antibacterial activity at the time of the surgical procedure. (See [Tables 55-5](#) and [55-6](#) and the Drug Formulary, [Appendix 8](#), for a list of dosages.)

The duration of surgery has a major influence on the overall risk of wound infection.²⁸ Drying of tissue and airborne contamination are also major factors. Tissue counts of less than 100,000 organisms per gram of tissue are needed to ensure proper incisional healing. Bacterial counts may double during each additional hour of operative time. Nosocomial infections develop in 1% of patients after procedures lasting less than 30 minutes and in 14% after procedures lasting more than 3.5 hours. In a study of dogs and cats the risk for postoperative infection was 2 times higher for those undergoing procedures lasting 90 minutes than for those undergoing procedures lasting 60 minutes.⁶ Ultra-clean surgical rooms have been shown to reduce the prevalence of postoperative infection; however, in most operating rooms with high-volume air exchange and perioperative antimicrobial use in extended procedures, the risk of postoperative infections can be minimized. For each additional person in the operating room, the risk of surgical-site infection in dogs and cats was 1.3 times greater.^{74a}

Localized infections in areas far from the surgical site can spread to operative wounds hematogenously. Bacterial translocation denotes the spread of viable bacteria from the lumen of the GI tract into the blood stream via the portal circulation. Manipulation of the intestines during surgery may lead to distant postsurgical infection or sepsis. The majority of culturable translocating bacteria in mesenteric lymph nodes and blood are *E. coli*.³⁴ In corresponding experiments, anesthesia without intestinal manipulation produced minimal bacteremia. Prolonged fasting (greater than 48 hours) before and after surgery caused increased bacteremia in animals with intestinal manipulation, presumably because of intestinal stasis and bacterial overgrowth. Bacterial translocation also increases with endotoxemia, abdominal irradiation, splenectomy, biliary obstruction, and hemorrhagic shock.

Host immunosuppression by a concurrent disease or an inherent immunodeficiency disorder may increase the risk of postoperative infection. In a study of dogs that were immunodeficient because of treatment with glucocorticoid and azathioprine had a higher prevalence of infected vascular grafts than immunocompetent dogs.² Diabetes mellitus, hyperadrenocorticism, obesity, and malnutrition are predisposing factors. An immunodeficient state may be induced in traumatized animals as a result of hemorrhage, glucocorticoid therapy, and reduced cell-mediated immunity from cytokine dysregulation. Previous urinary outflow obstruction has been shown to predispose cats to a higher risk of postoperative infection after perineal urethrostomy than cats without obstruction that are having the same surgery.¹⁸ Although anesthesia has been associated with in vitro alterations in leukocyte chemotaxis, mobility, and lymphocyte stimulation, actual documentation of impaired host immune responses in vivo has not been confirmed. Bacterial colonization of suction tips was a source of infection during surgery in dogs and cats.³⁷ Staphylococci were the most common contaminating organisms, and they appeared to originate from operating room air.

Delayed wound healing caused by excessive numbers of sutures, foreign implants, or devascularized tissues can serve as a focus for infection after contamination.² Dead space between tissues should be avoided, and all surgical wounds should be closely approximated. Although surgically placed drains allow for removal of blood or pus from dead space areas, they may delay closure or allow entry of organisms into wounds. Intravenous (IV) catheters and

Infectious Diseases of the Dog and Cat, 3rd Edition

intubation used in trauma patients or those that have undergone surgery also increase the risk of infection. Drains and IV catheters should be removed as soon as possible during the recovery period to minimize the direct or hematogenous colonization of the surgical site.

Prolonged hospitalization increases the risk of infection with antimicrobial-resistant bacteria. Wet dressings reduce the fibrin seal formation on a wound and may allow for the maceration of tissue and proliferation of bacteria at the incision site. Prophylactic antibiotics should not be used indiscriminately during surgical procedures and should only be used when contamination of tissues is expected (see Antimicrobial Prophylaxis in this chapter).

55.2 CLINICAL FINDINGS

The signs of infection are often masked in the traumatized patient, and complicating infection should be considered when any clinical signs worsen. Fever and leukocyte changes are not always predictive of infection. Some local inflammation or serous discharge should be expected at the incision site of any surgical procedure. A diagnosis of posttraumatic infection can be made from soft tissue swelling, hyperesthesia, fever, and leukocytosis. Additional signs that may be associated with systemic infections are increased respiratory distress, hyperglycemia or hypoglycemia, renal failure, thrombocytopenia, icterus, and severe mental depression.

55.3 DIAGNOSIS

Postsurgical infections are characterized locally by heat, swelling, pain, and erythema at the incision site. Unfortunately, the same signs may be part of the initial healing phases after surgery. Systemic manifestations of infection, such as rectal temperature elevations and leukocytoses or left shifts in the hematologic test findings, are more indicative of infection. A correlation has been made between elevation of rectal temperature 24 hours postoperatively and increased duration of surgical procedure.⁴² However, an elevation of the rectal temperature the day after surgery does not always indicate the development of wound infection. A wound is considered infected if during the postoperative period (1) discharge from the incision site is found, or (2) dehiscence develops in one or more wound layers and is accompanied by drainage, warmth, or swelling (Fig. 55-1). Wounds involving intestinal perforation and burns are always contaminated and therefore require immediate attention. With deeper wounds, radiographs of the skeleton or ultrasonograms of the soft tissues may reveal deeper tissue damage, soft tissue swelling, or gas formation. With chronic orthopedic infections, bony lysis, bone proliferation, or sequestra develop. Cytology of exudates and biopsy or culture of tissues is most definitive. Deep-sample culturing of infected wounds must be performed with surgical entry or needle penetration because surface contaminants are common. Material obtained in this way should be sealed in an airtight container and submitted to a laboratory as soon as possible so that the anaerobic agents that often are present can be cultured.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 55-5 Indications and Drugs for Antimicrobial Prophylaxis or Treatment in Surgery

SURGICAL CLASS	EXAMPLES	ASSOCIATED BACTERIA	RECOMMENDED THERAPY ^{ae}	
			FIRST CHOICE	ALTERNATIVES
Prophylaxis				
Clean	Routine surgery	None	None	None
Clean contaminated	Genital surgery	Aerobes: gram-negative Anaerobes	Cefazolin ^b	Fluoroquinolone
	Prolonged (> 3 hrs) surgery, orthopedic prosthesis, amputation, open fracture reduction	<i>Escherichia coli</i> , staphylococci, streptococci	Cefazolin ^b	β-lactamase-resistant penicillin
	Intra-abdominal	Aerobes: gram-negative Anaerobes	Cefoxitin ^c	Gentamicin, metronidazole
	Dentistry	Aerobes: gram-positives and anaerobes	Cefazolin ^b	Ampicillin, amoxicillin, chloramphenicol
Contaminated	Bite wounds	Aerobes and anaerobes	Ampicillin or amoxicillin-clavulanate	Clindamycin
	Enterotomy with leakage, abdominal trauma	Aerobes: streptococci, enterococci Anaerobes: bifidobacteria, clostridia, fusobacteria, <i>Bacteroides</i>	Cefoxitin ^c	Aminoglycoside, metronidazole
	Biliary infection cholecystectomy	Enterobacteriaceae (<i>E. coli</i> , <i>Klebsiella</i> , <i>Proteus</i>), <i>Bacteroides</i> , <i>Clostridium</i>	Cefoxitin ^c , cefotaxime ^d	Gentamicin
	Colonic resection ^a	<i>E. coli</i> , <i>Bacteroides</i>	Neomycin and metronidazole preanesthesia, and enemas	Cefoxitin, gentamicin, clindamycin
Treatment				
Infected	Abscesses	Aerobes	Ampicillin or amoxicillin-clavulanate	Aminoglycoside, clindamycin
	Ruptured bowel, colonic leakage	Anaerobes	Cefotaxime ^d	Metronidazole
	Pyometra	Aerobic and anaerobes	Cefazolin ^b	Fluoroquinolone

a For additional information, see Drug Formulary, [Appendix 8](#).

b Can substitute another first-generation drug; see also [Table 34-4](#) and Drug Formulary, [Appendix 8](#).

c Can substitute another second-generation drug; see also [Table 34-4](#) and Drug Formulary, [Appendix 8](#).

d Can substitute another third-generation drug; see also [Table 34-4](#) and Drug Formulary, [Appendix 8](#).

e Oral therapy starting 48 hours before surgery and before anesthesia includes neomycin and metronidazole, along with enemas for cleaning. Parenteral cefoxitin may also be given during the procedure. Routine prophylaxis not recommended with soft tissue (cyst removal, laparotomy not involving a viscus, inguinal hernia repair, mastectomy, tonsillectomy, simple lacerations); neurologic (laminectomy, fenestration); ophthalmic (lens extraction); orthopedic (rhinotomy or rhinoplasty).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 55-6 Recommended Preoperative Therapy for Surgical Prophylaxis

DRUG ^a	SPECIES	DOSE ^b	ROUTE	TIMING (MINUTES PREOPERATIVELY)	ANTIBACTERIAL SPECTRUM AND INDICATIONS
Penicillin G	D	40,000 U/kg	IV	30	Gram-positive and anaerobic bacteria, with some antibacterial resistance noted among isolates
Amoxicillin-clavulanate	D	10–20 mg/kg	PO	30	Most gram-positive and gram-negative aerobes and anaerobes;
	C	13.75 mg/kg	PO	30	first-choice drug for most bite wounds
	C	10–20 mg/kg	PO	30	Some gram-positive and gram-negative aerobes
Ampicillin, (amoxicillin)	B	22 mg/kg	PO	30	Some gram-positive and gram-negative aerobes
	B	11–22 mg/kg	SC, IV	30	Gram-positive and gram-negative aerobes and anaerobes
Ticarcillin	D	20–50 mg/kg	IV	30	Gram-positive and gram-negative aerobes and anaerobes
Cefazolin ^c	B	20–30 mg/kg	IV	16–60	First-generation drug: gram-positive aerobes, oral, gastroduodenal; and orthopedic surgery; clean surgery
Cefoxitin	B	30 mg/kg	IV	16–60	Second-generation drug: gram-negative aerobes
Cefotaxime	B	15–30 mg/kg	IV	16–60	Third-generation drug: gram-negative aerobes or anaerobes; ileocolic and gynecologic surgery
Clindamycin	B	5–11 mg/kg	PO	16–60	Gram-positive aerobes and anaerobes
Metronidazole	B	10 mg/kg	PO, IV	16–60	Anaerobes

B, Dog and cat; D, dog; C, cat; IV, intravenous; PO, by mouth; SC, subcutaneous.

a For additional information, see Drug Formulary, [Appendix 8](#).

b Dose per administration at specified interval.

c Drug concentrations of greater than 4 µg/ml were achieved in the surgical wound by using 20 mg/kg every 6 hours.³³ A second dose is given if the surgical procedure lasts longer than 90 minutes.⁴⁶ (See [Table 34-4](#) for a review of the cephalosporin-generation drugs.)

Infectious Diseases of the Dog and Cat, 3rd Edition

55.4 THERAPY

Tables 55-4 and 55-5 describe drug indications and recommendations for surgical prophylaxis. Extensive debridement or surgical drainage of wounds may be required to prevent wound infection and reduce extensive swelling or abscess formation. Wounds should be covered to prevent extensive drying of devitalized tissues, and drainage should be encouraged by incomplete closure or drain placement. Occlusive dressings containing adequate absorbent material should be changed whenever drainage is present. To encourage formation of sufficient granulation tissue, limbs should be immobilized or supported. Chronic nonhealing scar tissue should be resected from the wound. Prolonged hospitalization and indiscriminate use of topical or systemic antibiotics favor the overgrowth of resistant bacteria. Surgical drains, IV catheters, and intubations in trauma patients also increase the risk of infections. For intraabdominal infections and suspected or documented ruptured viscus, antimicrobial therapy should be provided to combat fecal flora, including anaerobes and gram-negatives such as Enterobacteriaceae species (see Intraabdominal Infections, [Chapter 89](#)). For orthopedic injuries with mandibular and maxillary or open fractures, penicillins or cephalosporins, respectively, are often administered. If implants are involved, stabilization, irrigation, antimicrobial carriers, implant removal, or wound debridement is often indicated.¹¹

529

55.5 PREVENTION

530

55.5.1 Skin Disinfection and Wound Irrigation

Antiseptics are important for reducing the prevalence of postoperative infections. Tincture of chlorhexidine (0.5% in 70% ethanol), povidone-iodine (0.75% available iodine), and detergents of chlorhexidine (4%) or iodine are the most commonly used agents for skin preparation.^{30,32} Alcoholic solutions of chlorhexidine are preferable to aqueous preparations because the alcohol is bactericidal and promotes drying of the exposed lesions. Various formulations of povidone-iodine have no deleterious effects on wound healing.¹⁷ Chlorhexidine diacetate as a 0.05 % w/v nondetergent antiseptic solution has been used to lavage open wounds and prevent contamination of dog tissues with *Staphylococcus intermedius*.²⁵ Chlorhexidine gluconate and alcohol were equally effective as stabilized glutaraldehyde, with or without alcohol, as a presurgical skin disinfectant in dogs.^{143a} Chlorhexidine solution has been more effective than povidone-iodine as an antibacterial treatment.^{24,35} In some instances, povidone-iodine solutions have harbored such organisms as *Pseudomonas*. In addition, the iodophors have less residual antibacterial activity than chlorhexidine. Despite its effectiveness, chlorhexidine can be irritating to intraarticular structures.¹ Although effective, hexachlorophene is no longer used because of its potential neurotoxicity in animals and people. Traumatic wounds are commonly irrigated with sterile saline. However, in a study with children, lacerations had the same infection rate whether irrigated with sterile saline or running tap water,⁴¹ suggesting that physical flushing is more important in contaminated traumatic injuries to reduce bacterial levels. With regard to tissue injury, Ringer's lactate has been less traumatic than normal saline or tap water to canine connective tissues in vitro,⁸ so it might be the most desirable flush solution to preserve tissue healing (see Bite Wound Infections, [Chapter 53](#)).

55.5.2 Surgical Equipment Disinfection

The disinfection of surgical tools and facilities is an intimate part of the operative procedure. (See [Chapter 94](#) for a review of hospital and equipment disinfection procedures.) The animal's hair should always be shaved and

Infectious Diseases of the Dog and Cat, 3rd Edition

its skin prepared for surgery before it enters the operating room. Care should be taken not to injure the skin during the clipping procedure. Surgical equipment should be appropriately sterilized using steam autoclaves or ethylene oxide rather than cold disinfection and should be stored in dust-free, enclosed cabinets. Cold disinfection should be avoided when possible because it may be associated with an increased risk of infections from soil saprophytes such as *Clostridium tetani* (see [Chapter 43](#)). All surfaces in operating rooms that do not contact the patient should be routinely disinfected with phenolic compounds. Floors can be washed with disinfectants and wet mopped or polished. Wet mops or vacuums with filtered exhaust elements can pick up excess disinfectant and loose debris. Built-up disinfectant films can be removed with a solution of 0.12 L (one-half cup) of vinegar in 3.8 L (1 gallon) of water. Dry mops and brooms should never be used to clean hospital floors because they disseminate microorganisms in dust. Personnel should wear face masks to minimize aerosol contamination in surgery areas. Washing hands and wearing gloves are superior to hand washing alone in minimizing the spread of skin microflora to the patient during surgery. Antisepsis of the skin at the incision site is similar to the procedure used to prepare IV catheter sites, but a final application of tincture of iodine or iodophor solution is used just before the animal is draped. (See [Chapter 94](#) for a discussion of cleanliness and sterility of anesthesia and nebulizer equipment.)

Fig 55-1 Secondary closure in a wound contaminated by bacteria. At this stage, the area must heal by secondary granulation tissue.

55.5.3 Lavage

Contaminated wounds should be lavaged with copious amounts of prewarmed saline solution. Pressure is delivered by a 35-ml syringe and 18-gauge needle or similar size catheter. Lavage without jet irrigation is not effective. Local antibiotic instillation may achieve higher concentrations of drugs in the desired tissue with minimal toxicity. Because antibiotics are readily absorbed, they should not be instilled in body cavities. Chlorhexidine has been used as a successful wound disinfectant.

Infectious Diseases of the Dog and Cat, 3rd Edition

55.5.4 Antimicrobial Prophylaxis

A majority of nosocomial infections occur in hospitalized animals undergoing surgery. Preoperative and intraoperative antimicrobials have been shown repeatedly to reduce the prevalence of postoperative infection when strict antisepsis cannot be maintained, such as during surgery of the bowel, respiratory, or biliary tracts or of the oropharyngeal region. (See [Chapter 89](#) for a discussion of prophylaxis during dental procedures.) Organisms that contaminate relatively avascular subcutaneous tissues, bone fragments, or serosal surfaces are often commensals of skin and mucosal surfaces. In certain surgical situations, antimicrobial therapy administered before the procedure for an anticipated infection may be beneficial (see [Table 55-5](#)). Antimicrobial prophylaxis was not better than placebo in decreasing infection rates for short-term, clean surgical procedures in dogs and cats performed by experienced surgeons.^{23,43} However, when veterinary surgical procedures required longer than 90 minutes, antimicrobial therapy was beneficial in reducing infection rates.⁴² In contrast, the administration of antibiotics significantly reduced the frequency of wound infection in clean surgical procedures performed by senior veterinary students.⁴² In human surgeries, procedures of more than 2 hours have been associated with a much higher prevalence of postoperative infection.³¹ Prophylactic antimicrobial therapy is beneficial in conjunction with surgical drainage of abscesses.

The success of prophylaxis depends significantly on the chosen antimicrobial (see [Tables 55-5](#) and [55-6](#)). Because of their low toxicity and effectiveness against the commonly infecting staphylococci, cephalosporins have been the mainstay of prophylaxis for surgery. Because of its prolonged duration of activity, cefazolin has been a popular choice among surgeons.

530

The timing of administration of antibiotics is an important factor in the prevention of surgical wound infections. The success involves timing the administration of the drug slightly before (less than 1 hour) or during the surgery to achieve the maximum possible concentration during the operative procedure and not continuing the administration for longer than 24 hours after surgery. Parenteral infusion has been preferred for antimicrobial prophylaxis, with an optimal administration time of between 16 and 60 minutes, depending on the route of administrations before the first incision.¹⁵ Administration more than 1 hour before surgery is associated with lower drug levels at the time of incision. If antimicrobial prophylaxis is considered as an afterthought, it will *not* be effective.

531

Oral therapy is given 1 hour before, intramuscular injections one-half hour before, and IV therapy immediately at the beginning of the anesthetic induction as an IV bolus (see [Table 55-6](#)). With the exception of colonic surgery, in which prophylaxis is started earlier, the initial dose of a systemically administered drug should be given parenterally at the time of anesthetic induction. For colonic surgery, systemic antimicrobial therapy combined with mechanical cleaning of the large bowel to reduce the microflora is started 48 hours before surgery. Enemas with isotonic lavage fluids and cathartics are often used.

Even with clean surgeries, the operating field is considered to be contaminated if the procedure lasts longer than 3 hours. Another dose of antimicrobial should be given at that time to maintain concentrations during the operation. Providing another dose of the drug at the time of closure may be needed if the procedure takes longer than 3 more hours. Antimicrobials penetrate formed tissue exudates and blood clots poorly but are readily incorporated into clots if they are present in the plasma during the clot formation. The risk of contamination is present until a firm fibrin seal forms between the wound edges 3 to 5 hours postoperatively. For this reason a final dose of antimicrobial is recommended during contaminated procedures when the closure is being completed. Perioperative antimicrobials should be chosen based on the procedure being performed and the

Infectious Diseases of the Dog and Cat, 3rd Edition

contaminants most likely to enter the wound site. Specific dose and frequency guidelines are available based on the pharmacokinetic and pharmacologic variables of the chosen antimicrobial.

When contamination is suspected but infection is not documented, antimicrobial therapy should never be given for more than 12 to 24 hours after surgery. Measures should be taken to reduce the risk of infection after antimicrobial prophylaxis because infection with resistant organisms is more likely. Hospitalization, stress, and invasive procedures should be avoided in immunosuppressed patients. If perioperative antibiotics are used, they should be bactericidal drugs with effectiveness that is limited as much as possible to the suspected contaminant (see [Table 55-6](#)). Systemic antibiotics are thought to enter host tissues at the time of surgery and should be maintained at high concentrations during the entire procedure. A full course of antibiotics at the proper dosage should be provided; anything less is often ineffective in animals with an adequate immune system. If results of susceptibility testing conflict or indicate that organisms are not susceptible to a particular drug, antibiotics should not be changed if the patient appears to be responding.

Antimicrobial chemoprophylaxis has several disadvantages, some of which are so serious that the risks might outweigh the benefits. For example, bacterial resistance or drug toxicities may develop. In addition, chloramphenicol may interfere with barbiturate metabolism, some cephalosporins (cefamandole, cefoperazone, and cefotetan) may cause hypoprothrombinemia, and aminoglycosides may cause neuromuscular blockade or nephrotoxicity. Prophylaxis with antimicrobials may suppress normal microflora and increase the risk of infection with resistant microorganisms (superinfection). Multiple antibiotic-resistant bacteria such as enterococci, staphylococci, and *Klebsiella* species have been isolated that have increasing levels of resistance. (See Antimicrobial Chemotherapy, [Chapter 34](#), and the Drug Formulary, [Appendix 8](#), for additional information on drugs and their dosages.)

56 CHAPTER 56 Laboratory Diagnosis of Fungal and Algal Infections

Spencer S. Jang

Richard L. Walker

Specific diagnosis of fungal and algal infections in animals requires laboratory procedures that include direct microscopic examination and culture, frequently supported by serologic tests. Many such direct examinations and primary cultures and some serologic tests are now well within the scope of in-office diagnostic procedures for veterinary practice. The development of improved methods for mycologic diagnosis is directed at rapid procedures using prepackaged identification kits and reagents, serologic kits, automated systems, and molecular techniques.¹⁶ In a high proportion of such cases, confirmation by a specialty laboratory will still be necessary to establish a definitive diagnosis. Refer to [Appendix 5](#), Laboratory Testing for Infectious Diseases of Dogs and Cats.

56.1 SPECIMENS FOR LABORATORY DIAGNOSIS

A satisfactory sample should be representative of the focus of infection and of adequate size to permit direct examination and culture. Except in systemic infections suggesting fungemia and requiring blood culture, samples should be obtained from the site of infection as indicated by lesions, signs, or symptoms. Because systemic mycoses are usually acquired via the respiratory tract, lung tissue or airway exudates are preferred samples. In certain disseminated mycotic infections, urine may also be an appropriate specimen to culture.

56.2 SAMPLE COLLECTION

When collecting skin scrapings for dermatophyte culture, clean the lesion, particularly the periphery, with 70% alcohol. Avoid using iodine, which is harmful to dermatophytes. Surface antisepsis, when feasible, aids in minimizing the collection of environmental bacterial and fungal contaminants and thereby ensures a meaningful result. Before venipuncture, the skin must be disinfected by swabbing with 70% alcohol followed by 2% iodine.

Scrapings for dermatophyte culture are best obtained with a scalpel blade or the edge of a glass microscope slide from the marginal, most active portion of the ringworm lesion. Use of a Wood's lamp may identify hairs infected with certain dermatophyte species. The hair roots are then plucked with forceps for culture. Nails are collected by clipping. The surface of heavily keratinized structures is scraped away for access to deeper portions. Claw surfaces are disinfected with alcohol. The surface of skin pustules, nodules, vesicles, and so forth is disinfected, and aspiration is done with sterile needle and syringe. A biopsy may be required if fungi fail to grow from the aspirate, scraping, or swab. Normal tissue, along with portions from all zones of the lesion, should be taken. Opened skin lesions are not disinfected or cleaned because such procedures may remove or kill the organisms of interest.

Swabs are of limited value in fungal isolation, and their use is discouraged. If no alternative collection method is available, specimens received on swabs in a suitable transport medium (see [Chapter 33](#)) should be cultured without delay. Swabs for direct smears, preferably, should not consist of cotton because recovery rates are poor, and inexperienced observers may mistake cotton fibers for hyphae.

Blood for cultures are collected directly via syringe and needle into conventional and biphasic blood culture bottles, automated blood systems, and lysis-centrifugation systems (see [Isolation](#)).^{1,11} A fresh needle is used for transfer of blood, 1 ml per 9 ml of culture medium, from syringe to the culture bottle. Blood samples taken from indwelling intravenous (IV) catheters are not recommended.^{1,11}

Infectious Diseases of the Dog and Cat, 3rd Edition

Urine is best taken by percutaneous cystocentesis, which ensures a sample uncontaminated by bacterial or fungal flora in the lower genitourinary tract (see [Chapter 91](#)).

Stool specimen cultures for diagnosis of fungal infections of the gastrointestinal tract are generally misleading. Biopsy specimens for histologic examination is best.

Fluids and contents of abscesses are collected through aspiration by needle and syringe. Large volumes, adequate for centrifugation, are best. Any granules should be included and characterized. Bone marrow is similarly sampled by needle and syringe or core needle biopsy. At least 3 ml of cerebral spinal fluid (CSF) is desirable via lumbar or cisternal puncture. For lung sampling, a transtracheal or bronchial wash or bronchial brushing is done (see [Chapter 88](#)).

Necrotic material or curettings and other surgically collected material should be handled aseptically pending examination and culture. Corneal lesions are sampled by scraping several times with a sterile Kimura spatula or nylon brush (see [Fig. 93-9](#)). Slide preparation and culture are done at the site and time of collection.

56.3 TRANSPORTATION AND PRESERVATION

For referral to a diagnostic laboratory, tissue and fluid samples should be shipped by the most expeditious route in secure, sturdy, leak-proof containers. Accompanying information on the type of sample being submitted and any clinical information and other circumstances will assist the laboratory clinician in selecting methods of processing the sample, including appropriate media, incubation conditions, and safety precautions.

533

Specimens that cannot be promptly processed can be held in a suitable bacterial transport medium (see [Chapter 33](#)). They are refrigerated at 4° C but not frozen for periods of up to 12 to 15 hours. Refrigeration may delay proliferation of slow-growing fungi for 1 to 2 days. *Aspergillus* and zygomycetes are sensitive to refrigeration. If a specimen suspected of harboring a zygomycete cannot be promptly cultured, overnight storage at room temperature in a bacteriologic transport medium is permissible. Some fungi have been recovered from specimens up to 2 weeks in transit, but this type of delay is not recommended.

534

Urine specimens may be kept under refrigeration for up to 12 hours before culture. Most bacteria and yeasts will multiply in urine kept at room temperature. The Urine C & S Transport Kit (Becton Dickinson, Franklin Lakes, N.J.) delays growth of bacteria and *Candida albicans* for up to 48 hours at room temperature. Vaginal swabs in transport medium or aspirates may be held under refrigeration before processing.

Blood culture bottles or lysis-centrifugation tubes (see [Isolation](#)), if subject to delay in processing, can be held at room temperature for up to 16 hours. CSF and fluids from serous cavities and joints should be processed as soon as possible. The presence of proteins and carbohydrates in CSF contributes to its qualities as a maintenance medium. CSF should be held at room temperature if not cultured immediately.

Nasal curettings and excised polyps may be divided between sterile containers for culturing and jars of 10% buffered formalin for histologic preparation aimed at diagnosing rhinosporidiosis ([Fig. 56-1](#)). Impression or scrape smears of nasal tissue should be made before fixation of specimens (see [Fig. 83-3](#)). Tissue and bone marrow may be moistened with a small amount of sterile saline if transport is delayed.

Skin scrapings, nails, and hairs can be collected in a clean envelope or a sterile culture dish for mailing. Skin scrapings also can be held in place between glass slides taped at both ends. Such samples should not be kept in tightly sealed containers because resulting accumulation of moisture can lead to overgrowth by saprophytes. Storage is best at room temperature; refrigeration can be harmful for some dermatophytes.

Fig 56-1 *Rhinosporidium*. Section of nasal polyp, dog. Thick-walled proliferating spherules (H and E stain, $\times 500$). (Courtesy Spencer Jang, University of California, Davis, Calif.)

56.4 PROCESSING OF SPECIMENS

The complete processing of specimens involves direct microscopic examination, isolation, identification, and serology. In the following sections, some of the procedures are considered, with particular reference to their feasibility as in-office tests. No special equipment, beyond that required for basic clinical bacteriology, is needed for fungal diagnosis. For incubation purposes, an undisturbed area where room temperature (approximately 25° C) remains fairly constant is adequate. A hand lens (8 to 10 \times) or a dissecting microscope is helpful in the early recognition of fungal colonies.

56.5 Direct Examination

The search for diagnostically significant fungal structures may involve preparation of stained or unstained wet mounts, fixed stained smears, and histologic sections. Some of these techniques are simple and rapid and may provide the clinician with a presumptive or even definitive diagnosis and a time-saving guide to therapy ([Table 56-1](#)).

56.5.1 Wet Mounts

Specimen material may be suspended on a slide in saline, water, or, preferably, 10% potassium hydroxide (KOH), which clears the preparation of tissue admixtures, leaving fungal elements intact. Examination should

Infectious Diseases of the Dog and Cat, 3rd Edition

begin under low power (100×) and with subdued light, with the condenser racked down to achieve maximal contrast. When structures suggestive of fungal elements are seen, higher magnification (400×) is needed for confirmation.

The KOH digestion method is employed universally in preparation of cutaneous samples suspected of harboring dermatophytes (see [Chapter 58](#)). The hair or skin scraping to be examined is placed into a drop of 10% KOH on a clean slide ([Fig. 56-2, A](#)). Material may require soaking in KOH for a period before further processing. The crusty material is teased apart with forceps or dissecting needles and covered with a coverslip. Gently press the coverslip down to expel any bubbles. This preparation is passed over an open flame several times, but care must be taken not to boil the mixture. This slide is examined immediately for the presence of arthroconidia or fungal chains embedded in the material (see [Fig. 56-2, B and C](#)). If no organisms are initially observed, the slide is reexamined in 30 minutes. A mixture of 20% KOH and 36% dimethyl sulfoxide or 25% KOH or sodium hydroxide (NaOH) with 5% glycerol increases penetration and clarity of specimens. Nails may require up to 2 hours for better clearing.

India ink (Pelikan) or nigrosin (1% aqueous), when mixed on a slide with fluids or exudates containing *Cryptococcus neoformans*, provides a dark background that outlines the large capsules surrounding the yeast cells (see [Fig. 61-6,B](#)). Placing a drop of test material and a drop of India ink separately on a slide and then adding a coverslip will allow for a proper mixture gradient to form. Less than 50% of culture-positive human CSF samples are proved to be infected by this method.¹

Less generally available but useful methods of unstained wet mount study include phase microscopy, in which the visibility of fungal structures against a background of tissue debris is improved, and fluorescent microscopy, in which a specimen is prepared by mixing with an equal volume of 10% to 20% KOH and 0.5% calcofluor white (Difco, Detroit, Mich.) on a slide. The specimen is examined on a fluorescent microscope equipped with a 365-nm exciter filter and a barrier filter that will transmit light at 410 nm. The fungal wall will fluoresce brilliantly. This procedure would be available at commercial diagnostic laboratories. See [Appendix 5](#).

534

Table 56-1 Direct Examination of Fungi in Clinical Specimens

STAIN OR REAGENT	USAGE	TEXT FIGURES/DISADVANTAGES
Gram	Stains bacteria, yeasts, and other fungi	<i>Cryptococcus neoformans</i> (Fig. 56-3); <i>Malassezia pachydermatis</i> (Fig. 56-4); <i>Sporothrix schenckii</i> (Fig. 56-5); some fungi stain variably or not at all
Potassium hydroxide	Clearing tissue and cellular debris from variety of specimens to provide greater visibility of fungal elements	Dermatophytes (Figure 56-2); artifacts develop after preparation time; experience required
India ink	Observation for presence or absence of capsules of fungal cells against a dark background	<i>C. neoformans</i> (Fig. 61-6); problems of artifacts can occur in the stain, poor sensitivity
Calcofluor white	A fluorescent brightener binding to polysaccharide such as cellulose and chitin	Detects variety of fungal elements; requires a fluorescent microscope
Wright	Stain for cytologic examination of peripheral blood, bone marrow, body fluids, and organ impressions	<i>Histoplasma capsulatum</i> (Fig. 60-8); <i>Aspergillus</i> (Fig. 64-5); <i>Candida</i> (Fig. 65-1,A), <i>Prototheca</i> (Fig. 69-6); limited use
Gomori's methenamine silver	Detection of fungal elements in histologic section	<i>Candida albicans</i> (Fig. 65-5); not readily available to most clinical laboratories
Periodic acid-Schiff reaction	Detection of fungal elements in histologic section	<i>C. albicans</i> (Fig. 65-6); not readily available to most clinical laboratories
Hematoxylin and eosin	Routine histologic stain used for detection of some fungal elements	<i>Rhinosporidium</i> (Fig. 83-4); <i>Coccidioides immitis</i> (Fig. 62-8); <i>Prototheca</i> (Fig. 69-1); usually requires large numbers of fungi to be detected with this stain

56.5.2 Fixed Smears

Gram stain is commonly done on most routine clinical specimens and will detect most fungi. It is of limited use in differentiating fungi because most specimens will stain gram positive or unpredictably, and it produces distortion in cell morphology. Yeasts can often be detected because they retain the primary crystal violet stain (Fig. 56-3). Fungal cell walls often appear as unstained halos. The usefulness of Gram stain is generally limited to smears in which *Candida*, *Malassezia* (Fig. 56-4), *Geotrichum*, *Trichosporon*, or the yeast form of *Sporothrix* spp. (Fig. 56-5) is suspected.

Romanowsky-type stains, such as Wright, Giemsa Leishman's, and Diff-Quik, will stain many fungi, especially yeasts, and are the stains of choice for the tissue phase of *Histoplasma capsulatum* (see Fig. 60-8). As with Gram stain, fungal cell walls remain unstained by these procedures.

A modified periodic acid-Schiff (PAS) reaction is applicable to direct smears and colors mycotic structures and some other extraneous and tissue components selectively red. This application is beyond the scope of most routine office laboratory work but should be obtainable as a service through any histology laboratory (see Appendix 5).

Fluorescent microscopy has had some limited application in mycologic diagnosis. Currently, no fluorescent diagnostic reagents are available commercially, and no diagnostic services use this approach.

Molecular-based methods for the direct detection of fungal pathogens have advanced substantially in recent years and are finding their way into use in the clinical laboratory. At present, use of these methods is

Infectious Diseases of the Dog and Cat, 3rd Edition

predominately restricted to large clinical laboratories or reference laboratories because of the associated expense and technical complexity of the tests. Refer to [Appendix 5](#) for laboratories performing these tests.

The most common molecular methods for identification of specific fungal agents employ either nucleic acid hybridization, which use genus- or species-specific nucleic acid probes or nucleic acid amplification methods such as the polymerase chain reaction (PCR).¹⁶ PCR uses DNA primers to amplify specific segments of fungal genome from the sample. In some cases, PCR is coupled with the use of internal probes or restriction fragment length polymorphism analysis to improve sensitivity and specificity. Alternatively, DNA sequencing can be performed on fungal-specific, PCR products amplified directly from tissues or fluids using universal primers derived from conserved regions in the fungal genome. Once the DNA sequence is obtained, a database can be searched to determine what the sequence most closely matches. This method allows for identification of fastidious or noncultivable fungi.

56.5.3 Histology

Stained sections from biopsy and necropsy specimens often provide critical diagnostic information about mycotic infections. Routine hematoxylin and eosin stain permits detection of the tissue phase of dimorphic fungi causing systemic mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, cryptococcosis). With filamentous fungi, it may demonstrate hyphae in tissues, often providing an indication as to their septate or nonseptate nature and whether they are pigmented or nonpigmented, and thereby helping with their classification. More specific for fungi is the preferred Gomori's methenamine silver stain, which stains fungal structures brownish-black against a pale green background, or a PAS reaction, which makes mycotic elements appear dark red against a contrasting background, depending on the counterstain. Many laboratories use hematoxylin and eosin as a counterstain or hematoxylin alone, which permits better pathologic characterization of the lesion than do other procedures. Mayer's mucicarmine can be used to demonstrate capsules on *C. neoformans*.

Infectious Diseases of the Dog and Cat, 3rd Edition

56.6 Isolation

Inoculation of a suitably prepared specimen on any appropriate medium is required. Preparation of specimens may include centrifugation of fluid samples, grinding of biopsy and other tissues, surface sterilization of necropsy specimens by searing, repeated washing of granules from mycetomas with saline, or filtration of CSF and blood. Scrapings, swabs, and blood may be inoculated directly without further preparation.

Because many pathogenic fungi, when propagated on agar media, constitute airborne health hazards, laboratories often prefer tubes and bottles to Petri plates for isolation purposes. If plates are used, they should be secured with oxygen-permeable tape. All examinations of cultures producing aerial mycelium should be carried out in biologic safety cabinets. Most fungi grow on media used routinely in microbiologic diagnosis (Table 56-2). These media should be used when the sample is obtained from an uncontaminated site, such as the central nervous system, internal organ, or joints. These sites have no resident flora and are not exposed to the external environment. Samples originating from cutaneous sources or mucous membranes that harbor such flora are cultured on selective media that may contain broad-spectrum antibacterial and antimycotic agents (see Table 56-2) for the suppression of bacteria and nonpathogenic fungi, respectively. A low pH (no higher than 6.0) of the medium may further limit bacterial overgrowth. Yeasts can be selectively recovered from specimens heavily contaminated with bacteria by propagation on a medium of pH 3.5 to 4.0. Fungal cultures are optimally incubated at 25° C to 30° C. Incubation at 37° C allows bacterial overgrowth and causes failure of some fungal pathogens to grow. An atmosphere of 40% to 50% humidity is favorable for most fungi.

The Isolator system (Wampole Laboratories, Cranbury, N.J.) has improved the number and rate of fungal isolations from blood.¹¹ This system involves lysis and centrifugation of 10 ml of blood. The supernatant is removed from the upper stopper, and the concentrate is removed from the bottom stopper and plated. The isolation rates of *H. capsulatum*, *C. immitis*, and *C. neoformans* have improved with the Isolator.¹¹ Vented broth bottles used for bacterial blood cultures should not be expected to detect fungi other than certain yeasts. Biphasic bottles contain 50 ml of brain-heart infusion broth and brain-heart infusion agar. A biphasic bottle is inoculated with 10 ml of blood, vented, and incubated in an upright position. After daily examination, it is tilted so that the broth floods the agar surface. Automated blood culture systems have been used and are an efficient means for laboratories dealing with large volumes of blood cultures.

56.7 Identification

Microscopic morphology of fungal reproductive structures is the most helpful criterion for identification. Other criteria are macroscopic colonial features under different conditions of incubation, nutritional and metabolic properties, antigenic characteristics, and pathogenicity for experimental animals.

Agar cultures are examined daily during the first 2 weeks of incubation and twice weekly thereafter. Allow 4 to 6 weeks for slow-growing fungi. Some common zygomycetes (*Mucor*, *Rhizopus* spp.) grow rapidly and abundantly, filling a tube or Petri dish within 2 or 3 days. Fruiting bodies may be visible as black specks in the colorless mycelium (Fig. 56-6). Aerial mycelium is grossly less prominent but more intensely pigmented by the presence of fruiting structures with *Aspergillus* (Fig. 56-7) and *Penicillium* spp. (Fig. 56-8). Some fungi produce soluble pigment that diffuses through the medium (e.g., *Microsporum canis*). In others, pigment is confined to parts of the organism and may be best observed either on the surface or on the reverse side of the colony. The colonial surface varies according to mycelial growth patterns from smooth ("glabrous") to powdery, velvety, and cottony. Yeasts, which form no or little pseudomycelium, produce mucoid, creamy, pasty, or waxy colonies.

537

538

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 56-2 Isolation Media for Fungi

MEDIUM (COMMERCIAL SOURCE)	SELECTIVE FEATURES	PRINCIPAL USE/LIMITATION IN MYCOLOGIC DIAGNOSIS
Blood agar (Remel Labs, Lenexa, Kan.)	Highly nutritious for most fungi	General purpose, converts some dimorphic fungi to yeast form; noninhibitory, nonselective, easily overgrown
Potato flake agar (Remel Labs, Lenexa, Kan.)	Low pH, highly nutritious for most fungi	To induce sporulation of fungi
Inhibitory mold agar (Remel Labs, Lenexa, Kan.)	Gentamicin and chloramphenicol for bacterial suppression	General purpose; not for dermatophytes
Sabouraud's dextrose agar (Remel Labs, Lenexa, Kan.; marketed as SAB DUET with DTM in a two-compartment plate by Bacti-lab, Mountain View, Calif.)	Low pH, modest nutritional quality; addition of chloramphenicol and cycloheximide inhibits bacteria and some fungi	General purpose; added antibiotics for isolation from contaminated environment such as recovery of dermatophytes; cycloheximide inhibits <i>Cryptococcus</i> ; <i>Aspergillus</i> , <i>Scedosporium apiospermum</i> , (<i>Pseudallescheria boydii</i>), some <i>Candida</i> spp.; chloramphenicol inhibits some yeast
DTM (Remel Labs, Lenexa, Kan.; Bacti-lab, Mountain View, Calif.)	Gentamicin, tetracycline, and cycloheximide are inhibitors; glucose and phenol red are indicators	Isolation of dermatophytes, which turn yellow medium to red in 48 hours; not for sporulation; may produce atypical colonial growth; natural pigmentation obscured; nondermatophytes turn yellow medium to red eventually
RSM (marketed as DERM DUET with DTM in a two-compartment plate by Bacti-lab, Mountain View, Calif.)	Cycloheximide and chloramphenicol are inhibitors; glucose and bromothymol blue are indicators	For dermatophytes, which turn blue medium green early; prompt conidial and pigment development permits identification; color change of RSM not as intense as of DTM with some dermatophytes

DTM, Dermatophyte test medium; RSM, rapid sporulation medium.

Low-power (25 to 50×) microscopy helps in early detection of mycelial growth and such diagnostic features as macroconidia and microconidia of dermatophytes (Figs. 56-9, 56-10, 56-11). Once colonial growth is established, identification is based largely on microscopic examination for hyphal characteristics: septate versus nonseptate, pigmented (dematiaceous) (Fig. 56-12) versus nonpigmented (hyaline), and conidia and their supporting structures. This step obviously involves the opening of a culture vessel and should be done only by trained, experienced personnel and under conditions in which exposure to people and animals and contamination of the environment can be avoided.

At the in-office laboratory level, it is feasible to make *teased preparations* or transparent cellophane tape lactophenol aniline blue mounts (LPAB, Remel Labs, Lenexa, Kan.) from mold cultures by using appropriate precautions. Diagnostic features are usually better preserved in their natural interrelationships in cellophane tape mounts (Figs. 56-13 and 56-14). In the absence of a laminar flow biosafety cabinet, such attempts should be restricted to macroscopically positive dermatophyte cultures.

The slide culture procedure probably exceeds the capabilities of most veterinary practices and should be left to clinical laboratories. This procedure permits study of undisturbed fungal structures by using LPAB (Figs. 56-15 and 56-16).

The germ tube test allows rapid differentiation of *C. albicans* (see Chapter 65) from most of the other, usually nonpathogenic, *Candida* spp. Serum, 0.5 to 1 ml, is inoculated lightly with suspect growth and incubated at 35° C

Infectious Diseases of the Dog and Cat, 3rd Edition

for 2 to 3 hours. A drop of the suspension is then examined microscopically (100× and 400×) for the presence of germ tubes sprouting from yeast cells (blastoconidia) of *C. albicans* (Fig. 56-17).

538

541

Fig 56-13 *Paecilomyces* in culture. Ovoid chains of conidia attached to a phialide (arrow) that is usually tapered (not visible) (Lactophenol analine blue, ×2000). (Courtesy Spencer Jang, University of California, Davis, Calif.)

Fig 56-14 *Pseudallescheria boydii* (= asexual stage of *Scedosporium apiospermum*). Single elliptical conidia attached to tips of conidiophores arising along the hyphae (Lactophenol analine blue, ×2000). (Courtesy Spencer Jang, University of California, Davis, Calif.)

Fig 56-15 *H. capsulatum* in culture. Tuberculate macroconidia (Lactophenol analine blue, ×2000). (Courtesy Spencer Jang, University of California, Davis, Calif.)

Commonly used differential media include Czapek agar (Difco, Detroit, Mich.) for the differentiation of *Aspergillus* spp.; cornmeal agar for the demonstration of chlamydospores in *C. albicans* and their absence in most other *Candida* spp.; Trichophyton agars (Remel Labs, Lenexa, Kan.) for the identification of *Trichophyton* spp.² by their growth factor needs; Christensen's urea agar (Difco, Detroit, Mich) for production of urease by *Cryptococcus*, *Rhodotorula*, *Trichophyton*,² and *Trichosporon* spp. and CHROMagar *Candida* (Hardy Diagnostics, Santa Maria, Calif.) for culture and identification of *C. albicans*, *C. krusei*, *C. tropicalis*, and *Trichosporon* spp.⁶

For definitive identification of the dimorphic fungi *Coccidioides immitis*, *H. capsulatum*, and *Blastomyces dermatitidis* antisera are commercially available (ImmunoMycologies, Norman, Okla.) for use in agar immunodiffusion exoantigen test. The antigen is prepared from an extract of mycelial growth.^{7,10}

Fungal isolates can be identified to genus or species level, or both, by many molecular-based methods. Universal primers to regions in the 28S rRNA gene have been used in PCR to amplify DNA that is then tested with specific nucleic acid probes.¹² The use of a multiplex PCR approach for identification of a battery of commonly encountered yeasts and molds has also been described.⁹ Commercially available DNA probes such as the Accuprobe system (Genprobe Inc., San Diego, Calif.) are available for identification of the important fungal agents, such as *C. immitis*, *B. dermatitidis*, and *H. capsulatum*.

Infectious Diseases of the Dog and Cat, 3rd Edition

541

DNA sequencing of specific regions of the fungal genome can also be used for identification purposes. The ribosomal RNA genes are most commonly used because they contain conserved areas present in most fungi and therefore serve as sites for amplification of DNA from a variety of different fungi with a single pair of primers. The rRNA genes also contain variable regions that are used in sequence analysis for making the identification. At present, the most commonly used region is the D2 variable region of large subunit rRNA gene. Commercial sequencing kits are available (MicroSeq D2 rDNA Fungal Identification System, Applied Biosystems) that use this region, but the method is complex and generally relegated to use by reference laboratories that have access to DNA sequencing facilities. A few commercial laboratories provide nucleic acid sequencing services for identification of fungal isolates (Accugenix, Newark, Del. and MIDI Labs, Newark, Del.). Sequence analysis of the internal transcribed spacer (ITS) regions (ITS-5.8S rRNA-ITS2) has also been used to identify a large number of fungal species.⁵ Oomycetes in the genus *Pythium* and *Lagenidium* are not true fungi but produce fungal-like granulomatous diseases (see [Chapter 67](#)). PCR has been used to determine the specific cause of these infections.⁴ Real-time PCR has been used to test peripheral blood for the diagnosis of invasive aspergillosis in people.⁸ A panfungal PCR has been used to detect *Candida* and *Aspergillus* in the blood of people with suspected disseminated infections.¹³

Molecular-based test results should be combined with clinical findings and morphologic features of the agent in tissues or in culture, or both, before making a final diagnosis.

Among miniaturized prepackaged identification kits for yeast and algae isolates belonging to the genus *Prototheca* spp. isolates, the API 20C (bioMérieux Vitex, Inc., Hazelwood, Mo.), the Uni-yeast-tek system (Remel Labs, Lenexa, Kan.), and RapID yeast plus panel (Remel Labs, Lenexa, Kan.) are used.¹⁴ All rely on tests that are scored to yield a single profile code, which is listed in a code book and translates into a species name. Identification can be completed within 4 hours to several days and more conveniently and generally more rapidly than by conventional methods. Rapid multiple biochemical test systems lack the database for the more unusual yeasts. Automated systems such as Vitex Yeast biochemical card (bioMérieux Vitex, Inc., Hazelwood, Mo.)¹⁴ and Microbial Identification System (MIS), (Microbial ID [MIDI], Inc., Newark, Del.) require continued expansion and updating of the veterinary database for improved quality.

56.8 Serologic Testing

Reagents designed to detect antigens and antibodies in body fluids are becoming commercially available in increasing numbers. An antigen detection kit, the *C. neoformans* latex agglutination test (Meridian Diagnostics, Cincinnati, Ohio), is one of several kits available that has been adapted for use in office laboratories (see [Chapter 61](#), [Table 61-3](#), and [Appendix 6](#)). Testing for antigens for *Histoplasma capsulatum* is available on a commercial basis (see [Chapter 60](#) and [Appendix 6](#)).¹⁵ The accuracy of this procedure for use in dogs and cats is not known. An enzyme-linked immunosorbent assay has been developed for the serologic diagnosis of pythiosis (see [Chapter 67](#) and [Appendix 6](#)).⁴ For a discussion of serum antibody testing of particular fungal infections, see the respective chapters.

57 CHAPTER 57 Antifungal Chemotherapy

Craig, E. Greene

57.1 SYSTEMIC ANTIFUNGALS

Table 57-1 lists various systemic antifungal drugs and the circumstances in which they are used. Chapters 58 to 68 provide information on their use for specific diseases, and details on dosage and usage are given in the Drug Formulary, Appendix 8.

57.1.1 Griseofulvin

Griseofulvin is an orally administered antifungal drug produced by *Penicillium griseofulvum*. Absorption from the gastrointestinal (GI) tract is facilitated by addition of fat to the diet. The drug has also been improved by production of microsized and ultramicrosized formulations. Griseofulvin is effective against infections caused by dermatophytes but not yeasts.

Griseofulvin is deposited in the epidermal layers of the skin and dermal appendages as they are formed. Several weeks of therapy are required for complete drug distribution throughout cell layers and for inhibition of fungal growth. Resistance rarely develops during therapy. Despite its teratogenic effects, griseofulvin does not have deleterious effects on semen quality in dogs.¹³⁸

57.1.2 Iodides

A solution of 20% sodium iodide or 100% (supersaturated) potassium iodide has been given orally to treat cutaneous sporotrichosis (see Chapter 63). The mechanism of action of the iodides is uncertain because they are not directly toxic to *Sporothrix* species in vitro. Iodides are all less toxic than amphotericin B (AMB), which should be reserved as a second-choice drug or for disseminated disease. Iodism, manifested clinically as dermal eruption with hair loss, may occur as a result of therapy.

544

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 57-1 Systemically Used Antifungal Drugs

GENERIC NAME (TRADE NAME)	ROUTE	CLINICAL FORMULATION	INDICATIONS	
			FIRST	ALTERNATE
Griseofulvin (Fulvicin, Grisactin)	PO	Capsules, tablets, Suspension	Dermatophytosis	None
Sodium or potassium iodide	PO	Solution (20% NaI-100% KI)	Sporotrichosis	None
Amphotericin B (Fungizone, AmBiosome, Amphocil, Abelcet)	IV, SC	See Table 57-2	Rapidly progressive or severe systemic mycosis, systemic aspergillosis, sporotrichosis, or mucormycosis	Imidazole-resistant cryptococcosis or other systemic mycoses
Flucytosine (Ancobon)	PO	Capsules (250 mg, 500 mg)	In combination with amphotericin B for cryptococcosis	Systemic candidiasis
Miconazole (Monistat IV)	IV	Ampules (10 mg/ml in 20 ml)	Systemic mycoses	None
Ketoconazole (Nizoral)	PO	Tablets (200 mg)	Systemic mycoses in dogs, systemic aspergillosis, miscellaneous fungal infections	Adjunctive with enilconazole for resistant aspergillosis, systemic mycoses in cats, dermatophytosis
Itraconazole (Sporanox)	PO	Capsules (100 mg) Oral suspension (100 mg/10 ml)	Cutaneous sporotrichosis, systemic mycoses in cats and small dogs, miscellaneous fungal infections, malasseziosis	Adjunct with nasal aspergillosis, systemic mycoses if funds available, dermatophytosis
Fluconazole (Diflucan)	PO, IV	Capsules (50, 100, 150, 200 mg) Oral suspension (10 or 40 mg/ml in 35 ml) IV solution (2 mg/ml in 50 or 100 ml)	CNS, meningeal or ocular systemic mycosis	Systemic mycoses in cats, candidiasis
Voriconazole (Vfend)	PO	Capsules (50 mg and 200 mg) Oral suspension (40 mg/ml, 75 ml) IV solution (200-mg vial)	Invasive aspergillosis, CNS mycosis	Candidiasis
Terbinafine (Lamisil)	PO	Tablets (250 mg) Topical solution (1%)	Onchomycosis, aspergillosis	Miscellaneous mold fungal infections
Caspofungin (Cancidas)	IV	IV solution (50- and 70-mg vials)	Invasive and disseminated aspergillosis	None
PO, By mouth; IV, intravenous; SC, subcutaneous; CNS, central nervous system.				
For additional information on drugs and dosages, see Drug Formulary, Appendix 8 .				

Infectious Diseases of the Dog and Cat, 3rd Edition

57.1.3 Amphotericin B and Other Polyenes

AMB is a lipophilic polyene isolated from *Streptomyces nodosus* that binds to sterols in cell membranes of eukaryotic organisms and causes increased permeability and leakage of nutrients and electrolytes. Nystatin is another polyene and is applied topically (see Topical Antifungals in this chapter). AMB has greater binding affinity for ergosterol, the major sterol of fungal cell membranes, than for cholesterol, which is present in mammalian host cells. Because it is poorly absorbed across the GI mucosa or skin, AMB must be given parenterally (usually intravenous [IV]) for the treatment of systemic mycoses. Most of the drug is metabolized locally at tissue sites, and lesser amounts are excreted in the urine. Standard IV preparations contain lyophilized AMB combined with deoxycholate and buffer in a colloidal state (ABD). ABD has been diluted and given subcutaneously, which appears to delay its absorption and reduce its nephrotoxicity, allowing larger amounts of the drug to be given.⁸³ Lipid-based formulations are now available with lower toxicity ([Table 57-2](#)); however, merely giving ABD in a fat emulsion did not alter nephrotoxicity.^{109,139} In contrast, commercially prepared lipid-encapsulated formulations are taken up well into organs of the mononuclear phagocyte system where the organism resides; they accumulate at relatively low levels in the kidneys.^{4,73} Lipid-based formulations can be given at a higher dose and may be effective in treating resistant or ABD-unresponsive mycoses.¹⁰⁰ The overall dose rate for these drugs can be higher because of their lower toxicity. The cost of these lipid formulations is usually prohibitive for veterinary patients. Occasionally, the AMB formulations are used for topical therapy of mycotic disease. (See the Drug Formulary, [Appendix 8](#), for information about the various preparations and specific information regarding AMB use.)

The fungal organisms affected by AMB are listed in [Table 57-1](#). Zygomycetes (family Mucoraceae) are variably susceptible, and *Aspergillus* species are usually resistant. Because higher effective AMB dosage levels can be achieved, lipid-based formulations are more effective against zygomycosis and fusariosis, and they might be the first choice for treating these diseases.⁵⁴

AMB was the first line of therapy for rapidly progressive or disseminated deep mycotic infections. Resistance rarely if ever develops during treatment, but relapses may occur when the drug is discontinued. Oral azoles such as ketoconazole (KTZ), itraconazole (ITZ), and fluconazole (FCZ) have become alternatives for treatment of uncomplicated systemic mycoses.

Hamycin is another polyene that is effective against *Candida*, *Cryptococcus*, *Histoplasma*, *Blastomyces*, and *Aspergillus* species. It has been given orally, topically, and intraperitoneally to treat various mycotic conditions, although toxicity does occur. A dog with disseminated aspergillosis was treated with some success.⁶⁶ Liposomal encapsulation of this drug has been associated with increased efficacy and reduced toxicity.⁹³

57.1.4 Flucytosine

Flucytosine, or 5-fluorocytosine (FCY), is a fluorinated pyrimidine originally synthesized as an antineoplastic agent. It interferes with pyrimidine metabolism and resultant DNA synthesis in yeasts.

FCY is effective against *Cryptococcus* species, *Candida* species, and other yeasts but has little or no effect on other deep mycotic agents or on *Aspergillus* species. Localized candidiasis or cryptococcal infections respond best, but resistance to FCY frequently develops during therapy. For this reason, the drug is always given in combination with AMB. Skin eruptions similar to those caused by azoles have been observed in treated dogs.⁸⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

57.1.5 Azole Derivatives

Synthetic imidazole derivatives were originally produced as broad-spectrum anthelmintics with activity against some gram-positive bacteria and protozoa. Like AMB, they inhibit sterol synthesis via fungal cell cytochrome P-450 as one of their main effects, but they are generally less toxic. They also inhibit nucleic acid, triglyceride, and fatty acid synthesis and alter oxidative enzyme biochemistry. At low concentrations they are fungistatic, and at higher concentrations, which cannot be achieved systemically, they are fungicidal. When given systemically, they vary in pharmacokinetic parameters such as oral bioavailability, protein binding, plasma clearance, and volume of distribution (see Drug Formulary, [Appendix 8](#)). They all undergo hepatic metabolism by cytochrome P-450 enzymes. The metabolism can lead to drug interactions in which their level is decreased by coadministered drugs that reduce their absorption or accelerate their metabolism ([Table 57-3](#)). Unexpected toxicity of coadministered drugs may result because of their delayed metabolism (see [Table 57-3](#)). Of the imidazole group, thiabendazole was initially recognized as being effective in treating human dermatophytoses. Miconazole, clotrimazole, and enilconazole are available in creams and lotions and can be formulated into solutions for topical treatment of fungal infections of the skin, such as dermatophytosis and candidiasis (see Topical Antifungals in this chapter and Drug Formulary, [Appendix 8](#)). However, oral therapy with an azole, griseofulvin, or terbinafine, is needed for nail infections. Of the orally administered azoles, KTZ is an imidazole, whereas newer drugs are triazoles such as ITZ and FCZ. The orally administered azoles are becoming widely used in human and veterinary medicine to treat systemic and opportunistic fungal infections. Oral administration has been preferred in many situations because it is easier than IV administration of AMB. In vitro susceptibility testing of the drugs shows variable efficacy against different fungi, but it does not always parallel in vivo efficacy.

57.1.5.1 Ketoconazole

KTZ is less active than miconazole but is better absorbed from the GI tract, making it convenient for the treatment of systemic mycoses and chronic mucocutaneous candidiasis. Absorption is improved when taken with a meal or acid media, therefore antacids and H₂-receptor antihistamine antagonists should not be given concurrently. The drug is predominantly bound to plasma albumin, entering all tissues and body fluids in therapeutic concentrations with the exception of seminal, central nervous system (CNS), and ocular locations. The drug is distributed throughout the skin and subcutaneous tissues and therefore has been used in treating superficial fungal infections of the skin and hair. Metabolites of the drug, produced in the liver, lack antifungal activity.

Occasional nausea, partial anorexia, and vomiting in dogs can be overcome if the drug is given with meals and by dividing the daily dose into three or four administrations. Additional side effects of KTZ are similar to those of other azoles. Frequently, reversible subclinical increases in activities of hepatic transaminases and alkaline phosphatase in blood occur as manifestations of hepatotoxicity. Less commonly, clinical hepatitis develops, and if treatment continues or dosages are high enough, it may be fatal. Histologic findings in affected animals include enlarged portal tracts, bile duct proliferation, and infiltration with mononuclear cells. KTZ may produce endocrine dysfunction by suppressing testosterone and cortisol synthesis.

Table 57-3 Drug Interactions of Commonly Used Antifungal Drugs^{30,40,89}

DRUG	USE	ANTIFUNGAL DRUG INTERACTION	CLINICAL COMPLICATION
Cimetidine, ranitidine ^a	H ₂ -receptor antacids	ITZ, KTZ	Decreased azole absorption
Cyclosporine	Immunosuppressant	ITZ, KTZ, FCZ, VCZ	Nephrotoxicity of cyclosporine
Digoxin	Cardiac inotrope	ITZ	Digoxin toxicity
Phenytoin	Anticonvulsant	ITZ, KTZ, VCZ, FCZ	Increased azole metabolism; phenytoin toxicity
Felodipine, nifedipine, amlodipine	Calcium-channel blockers	ITZ	Edema, calcium-channel concentrations
Isoniazid	Antimycobacterial	KTZ	Increased azole metabolism
Lovastatin	Lipid control	ITZ, VCZ	Rhabdomyolysis
Midazolam, diazepam	Sedative	ITZ, KTZ, FCZ, VCZ	Sedation
Nortriptyline	Antidepressant	FCZ	Sedation, cardiac arrhythmias
Omeprazole ^b	Antacid	ITZ, KTZ	Decreased azole absorption
Phenobarbital	Anticonvulsant	ITZ, KTZ	Increased azole metabolism
Rifampin	Antibacterial	ITZ, KTZ, FCZ, VCZ	Increased azole metabolism
Terfenadine	Antihistamine	ITZ, VCZ	Cardiac arrhythmias, death
Sucralfate	GI-coating agent	ITZ, KTZ	Decreased azole absorption
Sulfonylureas	Hypoglycemic agents	ITZ, KTZ, FCZ, VCZ	Severe hypoglycemia
Zidovudine (AZT)	Antiretroviral	FCZ	Zidovudine toxicity

FCZ, Fluconazole; ITZ, itraconazole; KTZ, ketoconazole; VCZ, voriconazole.

Infectious Diseases of the Dog and Cat, 3rd Edition

- a Any antacid that raises gastric pH will interfere with absorption of azoles.
- b This interaction is used to increase the drug concentration of cyclosporine to help reduce the required dosages for treating perianal fistulas in dogs.

KTZ is most effective in vitro against yeast and dimorphic fungi such as *Candida*, *Malassezia*, *Coccidioides*, *Histoplasma*, and *Blastomyces* species and is less effective against *Cryptococcus*, *Sporothrix*, and *Aspergillus* species. Evidence suggests that in rapidly progressing systemic mycoses, such as in many cases of blastomycosis, patients should first be treated with AMB and then maintained on KTZ (see Amphotericin B and Other Polyenes in this chapter). The action of KTZ alone often occurs so slowly (over 5 to 10 days) that the disease progresses before the drug has a chance to take effect. In contrast, KTZ has been given alone in dogs and cats to successfully treat coccidioidomycosis and some cases of histoplasmosis and cryptococcosis, although relapses are common when host defenses are inadequate. Preference for more active and generally less toxic ITZ or FCZ has been apparent for treatment of these infections. If underlying immunosuppression is thought to be responsible for the fungal disease, concurrent treatment with AMB is recommended. No evidence suggests that KTZ provides synergistic effects with other antifungals except AMB, and even that evidence is inconclusive. (For dosing and detailed information on administration, see Drug Formulary, [Appendix 8](#), and [Chapters 58 to 68](#).)

Unfortunately, as noted with many of the other antifungal drugs, eradication of systemic fungi with azole drugs is often incomplete. Relapses can occur when maintenance therapy is discontinued. Infections in areas where the drug cannot easily reach such as bone and the CNS are especially difficult to treat. Therapy should always continue at least 4 weeks after disease is no longer detectable clinically.

57.1.5.2

Itraconazole

ITZ is a broad-spectrum azole with more potent activity than KTZ against *Candida* species, *Aspergillus* species, and dermatophytes. It can be given orally or parenterally and is widely distributed in body tissues other than the CNS. The best success in treating human patients has been in those with (in decreasing order) paracoccidioidomycosis, blastomycosis, sporotrichosis, noninvasive aspergillosis, meningeal cryptococcosis, and aspergilloma. Some patients with zygomycosis or other fungal infections also respond to ITZ treatment. In small animal practice, it has been most effective in treating blastomycosis (see [Chapter 59](#)), histoplasmosis (see [Chapter 60](#)), cryptococcosis (see [Chapter 61](#)), and coccidioidomycosis (see [Chapter 62](#)). ITZ seems to be less toxic than KTZ, probably because ITZ more selectively inhibits fungal rather than mammalian enzymes. Therefore unlike KTZ, ITZ has minimal effects on androgen or cortisol metabolism. Higher dosages should be expected to cause side effects similar to those of KTZ. Dosage adjustments do not appear to be necessary in the presence of renal dysfunction. Bioavailability after oral administration is erratic, but it can be maximized by giving ITZ with a food or fats. An oral solution improves absorption, especially in cats.⁹ An IV formulation is also available for treatment of severe resistant infections such as aspergillosis, and high, steady-state plasma concentrations can be reached without the loading period required for oral formulations (see Drug Formulary, [Appendix 8](#)).

57.1.5.3

Fluconazole

FCZ is an orally active agent that has been used to treat systemic mycoses, including cryptococcal meningitis, blastomycosis, and histoplasmosis and to treat superficial infections, including candidiasis and dermatophytosis. FCZ crosses the blood-brain and blood-cerebrospinal fluid (CSF) barriers better than the older azole derivatives. It is effective for treating cryptococcosis because of its CNS penetration.¹⁰¹

546

547

Infectious Diseases of the Dog and Cat, 3rd Edition

Voriconazole (VCZ), an FCZ derivative, also has excellent CNS penetration. The advantages of FCZ are that it is well absorbed orally and has a long half-life, making it valuable for treating susceptible fungal infections in various tissues. However, it generally is less active than ITZ, especially against filamentous fungi. It seems to be less toxic than KTZ. It is not very effective against *Aspergillus* species. Most FCZ is excreted unchanged in the urine, which makes it valuable for treating urinary yeast infections caused by *Candida* species.

57.1.5.4 Voriconazole

VCZ (Pfizer Ltd, Sandwich, UK) is a synthetic derivative of FCZ. VCZ is licensed for treatment of drug-resistant *Candida* and *Aspergillus* infections in people. It is the first among a second generation of triazoles, including posaconazole and ravuconazole, to be licensed. These three drugs have enhanced broad-spectrum antifungal activity against *Candida*, *Trichosporon*, *Cryptococcus*, *Histoplasma*, *Blastomyces*, *Aspergillus*, and *Fusarium* species and against some zygomycetes. The drugs have also demonstrated potent therapeutic efficacy in treatment of invasive pulmonary aspergillosis and disseminated and oropharyngeal candidiasis in experimental animals. This group of drugs is also effective against the filamentous fungi, and VCZ can penetrate the CNS barrier. VCZ has been more effective than AMB in the initial treatment of invasive aspergillosis in people,⁵³ but it has shown some tendency to produce hepatotoxicity in people.¹⁰⁸ (See Drug Formulary, [Appendix 8](#), for additional information on VCZ.)

57.1.5.5 Posoconazol

Posoconazol (PCZ, previously SCH 56592; Schering-Plough Inc, Kenilworth, N.J.), a hydroxylated analogue of ITZ, is least active against *Candida* species that are resistant to FCZ or ITZ. However, its in vitro activity against *Aspergillus* species is greater than that of ITZ and VCZ. Bioavailability after oral administration is good. It has been formulated as an oral tablet and suspension and is in clinical trials in human medicine. Preliminary trials in rodents with experimental pulmonary invasive aspergillosis have shown it to be superior to AMB or other triazoles reducing fungal burden compared.

57.1.5.6 Ravuconazole

Ravuconazole (RVZ; Bristol-Myers Squibb Inc, Wallingford, Conn.) is structurally similar to FCZ and VCZ. It has fungicidal activity and is 47% to 74% bioavailable, with absorption enhanced by food. In rodents with invasive pulmonary aspergillosis, it has been equally or more effective than AMB and the other triazoles.

57.1.6 Terbinafine

Terbinafine is an antifungal allylamine derivative that has been extremely effective for treating people with chronic dermatophytosis of the skin or nails and superficial yeast infections. High concentrations are reached in these tissues. Improvement or resolution of onychomycosis usually occurs after 3 to 6 months of therapy. Side effects have been minimal. This drug has potential value for treating canine and feline onychomycosis. Terbinafine has been used alone or in combination with other antifungals for treatment of aspergillosis and other filamentous fungal infections (see Drug Formulary, [Appendix 8](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

57.1.7 Inhibitors of Chitin Synthesis and Cell Wall Synthesis

Fungal cell walls are composed of polysaccharides, predominantly chitin, chitosan, glucan, and mannan. Newer compounds that are being investigated as systemic antifungals are the polyoxins and nikkomycins, drugs that inhibit chitin synthesis in the fungal cell walls. Nikkomycins are nucleoside-peptide antibiotics that are competitive analogues for a substrate of the enzyme chitin synthase and have effects similar to those of β -lactams on gram-positive bacteria. In vitro studies have shown marked efficacy against *Coccidioides* and *Blastomyces* species and lesser activity against *Candida* and *Cryptococcus* species. Filamentous fungi seem more resistant. Nikkomycin Z was less effective in many experimental fungal infections in rodents; however, combination therapy may be more beneficial.⁸² Lufenuron, a benzoylphenyl urea and chitin-synthesis inhibitor used to control fleas, has been reported to be effective in the treatment of dermatophytosis and coccidioidomycosis; however, in controlled studies the results have been equivocal (see [Chapters 58](#) and [62](#), respectively, and Drug Formulary, [Appendix 8](#)).^{3,7,8} The benanomycins and pradimicins damage the mannan component of the fungal cell wall by calcium chelation, but their use is limited by their poor oral bioavailability.

57.1.7.1 Echinocandins

Aculeacins, echinocandins, and papulacandins are lipopeptides that inhibit the synthesis of 1, 3- β -glucan, a polysaccharide in the cell wall of many pathogenic fungi. Together with chitin, ropelike glucan fibrils give the cell wall integrity and strength. One early echinocandin, cilofungin, was effective against systemic candidiasis and *Aspergillus* species in laboratory animals when given by continuous IV infusions. Caspofungin, micafungin, and anidulafungin have been most promising for clinical use.

57.1.7.2 Caspofungin

Caspofungin (MK-0991, L-743,872, *Cancidas*; Merck, Rahway, N.J.) has been approved for treatment of mucosal and invasive candidiasis and invasive aspergillosis in people refractory to AMB or triazoles. It is a fungicidal, water-soluble drug that must be given parenterally because of its low oral bioavailability. Metabolism is predominantly via the liver. Fungal growth is required, so the onset of action in vivo is slower than that of AMB. It has also been shown to be equal or more effective than AMB in treatment of invasive candidiasis.⁹⁴ This class of drugs has few side effects. The drugs are currently only available for IV infusion on a once daily basis. Interactions are apparent with other drugs that undergo hepatic metabolism. In vitro studies have shown an enhanced antifungal effect in the presence of sera or phagocytes, suggesting damage to hyphae is followed by enhanced fungicidal activity. Toxicity has been low in investigational studies in people. *Micafungin* (FK463; Fujisawa Healthcare, Deerfield, IL) has shown high in vitro activity against *Aspergillus* species that is greater than that of AMB or ITZ. Preliminary results in clinical trials have been favorable. *Anidulafungin* (VER-002, LY-303366; Vicuron, King of Prussia, Pa.) has the longest half-life of any of the echinocandins and has fungistatic activity that has been higher than AMB or ITZ during in vitro studies. In studies in rodents with invasive aspergillosis, anidulafungin in combination with glucocorticoids proved highly fatal.¹⁷ This is thought to be a complication that can occur with the any drug in the echinocandin class.¹²⁶

Infectious Diseases of the Dog and Cat, 3rd Edition

57.1.8 Combination Therapy

Simultaneous administration of antifungal agents is indicated in certain circumstances. Combined use of AMB and FCY is synergistic in treating cryptococcal infections; presumably, AMB facilitates penetration of FCY into the fungal cell. Synergism has also been subjectively assessed in the treatment of blastomycosis, coccidioidomycosis, and histoplasmosis by combining AMB and azole derivatives. Generally, AMB and azoles are started simultaneously in cases of rapidly advancing infection because of the 2- to 3-week delay of the azole derivatives to be effective. After this time the AMB may be discontinued. The therapeutic combination of ITZ and AMB as a combination for resistant infections is highly controversial. Lipophilic azoles such as KTZ and ITZ block the interaction of AMB with the fungal cell membrane.¹²⁹ Water-soluble azoles such as FCZ enter the fungal cell membrane and do not cause this interaction. Synergism between FCZ and AMB has been observed in treatment of systemic candidiasis, whereas combinations of echinocandins with azoles, AMB, or nikkomycins have not shown antagonism and deserve more study.⁴² In invasive aspergillosis, combination therapy using AMB and 5-FCY or AMB and rifampin was more efficacious than either drug alone and superior to AMB and ITZ.¹²⁷ Combinations of allylamine antifungals such as terbinafine and azoles have been more effective in vitro and in vivo than either drug alone.¹¹⁹ Fluoroquinolones appear to enhance the antifungal activity of AMB or FCZ.¹¹⁹

57.1.9 Immunotherapy

Disseminated fungal infections are often indicative of impaired host immunity. A direct relationship has been established between immunosuppressive dosages of glucocorticoids or cyclosporine and fungal dissemination. Glucocorticoids can suppress the ability of phagocytes to kill conidia through inhibition of nonoxidative processes and impairment of lysosomal activity.¹²⁶ Glucocorticoids predominantly suppress macrophages, whereas cytotoxic chemotherapy decreases neutrophil numbers and function. Recombinant hemopoietic cytokines such as G-CSF, M-CSF and GM-CSF reduce periods of neutropenia and the risk of developing invasive mycoses.^{96,112} Pretreatment of neutrophils or phagocytes with their respective stimulatory cytokines may reverse or attenuate the inhibitory effect on cytotoxic antifungal activity. Granulocyte transfusions have not been very beneficial in potentiating treatment of fungal infection in people unless donors have been primed with G-CSF. Therefore the effect of the cytokine may be critical in this facilitation. Leukocyte colony-stimulatory factors and additional cytokines such as interferon- γ (IFN- γ), which can enhance the activity of phagocytes against fungi, have shown some efficacy during in vitro and in vivo animal studies. Antifungal drugs combined with IFN- γ or interleukin-12 (IL-12) were synergistic in treating systemic infections in laboratory rodents.^{15,42} Antifungal therapy and immunotherapy have also been combined and may have a synergistic effect. Vaccines composed of whole *Pythium insidiosum* cells or concentrated soluble antigens have been used for treatment of infection in horses and dogs.⁵¹ The effectiveness of such immunotherapy requires additional investigation. IV immunoglobulin therapy may help reduce the prevalence of fungal infections in immunocompromised hosts; however, additional controlled studies are needed (see Immunotherapy, [Chapter 2](#), and Drug Formulary, [Appendix 8](#)).

57.1.10 Antifungal Drug Use in Pregnancy

Griseofulvin, FCZ, and KTZ are all teratogenic or embryotoxic in animals and should be avoided. KTZ also interferes with steroidogenesis and may alter sexual differentiation. Iodides may cause congenital goiter in

Infectious Diseases of the Dog and Cat, 3rd Edition

fetuses, thereby causing dystocias. AMB and its lipid preparations are not teratogenic and are probably the drugs of choice for systemic chemotherapy of pregnant animals. FCZ is safe at low dosages in pregnancy; however, higher levels produce congenital malformations. At higher than therapeutic dosages, ITZ produced maternal and embryotoxic effects and teratogenicity in rats and mice. Whenever possible, topical therapy for dermatomycoses is recommended during gestation.

57.1.11 Fungal Biofilms

Nosocomial fungal infections may be caused by organisms that have adapted to produce biofilms on inanimate objects, which allows them to infect or colonize patients that are hospitalized for various medical conditions requiring indwelling catheters, endoscopy, or invasive or prosthetic procedures. For example, *Candida* species biofilms have been identified on indwelling IV catheters (see [Chapter 65](#)). Once attached to the surface of the implanted device, the organisms can proliferate, forming dense colonies of yeasts, hyphae, or pseudohyphae. Subsequently, organisms detach, producing septicemia. The clinical significance of such infections is host and antimicrobial resistance.⁵⁹ The lipid formulations of AMB and the echinocandins have been shown to be most effective in penetrating these biofilm-associated infections.

57.1.12 Antifungal Resistance

An increased risk of invasive fungal infections such as aspergillosis has been noted in immunosuppressed people who received previous treatment with FCZ.¹²¹ Resistance of *Aspergillus* species to ITZ in vitro has been associated with up-regulation transporter genes, and previous treatment with FCZ has made *Aspergillus* species more resistant to the effects of AMB in vitro.⁷⁰ These observations suggest that indiscriminate antifungal prophylaxis for immunocompromised hosts may lead to more resistant fungal infections and should be avoided. The total cumulative dose of FCZ administered and the use of subtherapeutic intermittent dose schedules are the factors most likely to contribute to emergence of fungal resistance.¹⁴⁵

57.1.13 Adjunctive Surgical Therapy

Surgery is often needed to debride fungal infections in areas that are difficult for antifungal agents to penetrate. Fungal diskospondylitis may require debridement and stabilization of infected intervertebral lesions. Osteoproliferation does not often occur with such infections as with bacterial diskospondylitis. It is also difficult to eliminate infections in the testes or epididymis, so neutering is recommended when infection is detected in these tissues. Endogenous enophthalmitis often develops as a result of systemic fungal dissemination. Fungal infection localizes in the retinal vessels and choroid, with exudative lesions developing along blood vessels; later the infection spreads to the vitreous. The capillaries of the CNS and aqueous are nonfenestrated and as a result are more resistant to the entry of antifungal drugs. Early choroidal infections can be treated with systemic therapy. Even AMB cannot penetrate the inflamed eye. In such circumstances, AMB is sometimes injected directly into the vitreous. In some cases the vitreous or eye must be surgically removed. Of the azoles, FCZ is most lipid soluble and reaches intraocular concentrations between 25% and 50% serum concentrations. It is likely that higher-than-recommended dosages of FCZ may be needed for intraocular infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

57.2 TOPICAL ANTIFUNGALS

Many formulations are used in the treatment of dermatophytosis and superficial yeast infections ([Table 57-4](#); see Dermatophytosis, [Chapter 58](#)). Undecylenic acid is an unsaturated fatty acid given in combination with zinc to treat dermatophytosis. Its mechanism of action is unknown. Mercaptans—organic mercurial compounds—have been used as plant fungicides and can be a low-cost, dilute dip for affected animals. Tolnaftate, a synthetic lipid-soluble compound, has also been used, but hyperkeratotic plaques must be removed before its application to ensure its effectiveness. Topical cuprimyxin is a copper-containing compound that is highly effective against *Malassezia* species. Iodochlorhydroxyquin is a halogenated oxyquinoline that has been given orally as an antifungal, antiprotozoal, and antibacterial agent in dogs, although overdosages have caused CNS toxicity. Chlorhexidine solution (0.5%) has been recommended as a daily dip or shampoo for persistent dermatophyte infections, although its efficacy is poor.^{25,147} Haloprogin is a broad-spectrum topical antifungal drug that may be more helpful against dermatophyte and *Candida* species infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 57-4 Agents Commonly Used Topically Against Fungi and Yeasts

GENERIC NAME	CLINICAL FORMULATION (% ACTIVITY)	SUSCEPTIBLE ORGANISMS (MOST TO LEAST)	COMMENTS AND RECOMMENDATIONS FOR VETERINARY USAGE
Miscellaneous			
Mercaptans	Captan Technical-grade powder (45%)	Dermatophytes	Not recommended, toxic, carcinogenic, ineffective
Chlorhexidine	Nolvasan, ^a chlorhexiderm ^{a,b} solution (1%), shampoo (0.5%)	Dermatophytes	Poor efficacy
Tolnaftate	Tinactin ^c Cream, powder, solution, aerosol, liquid (1%)	Dermatophytes	Spot treatment: animals can ingest, bitter taste
Undecylenic acid and salts	Powder, ointment, cream, 2%–10% soap, liquid, foam ^c	Dermatophytes	Spot treatment: animals can ingest, bitter taste
Halprogin	Halotex ^d Cream solution (1%)	Dermatophytes, <i>Malassezia</i>	Spot treatment, ear medicant
Lime sulfur	Lymdyp ^b	Dermatophytes	Has odor, stains hair, good for dermatophytosis, very safe in puppies and kittens, stains jewelry
Ciclopiroxolamine	Loprox ^e Cream, lotion (1%)	<i>Malassezia dermatophytes</i> , <i>Candida</i>	Spot treatment
Naftifine hydrochloride	Naftin ^f Cream, gel (1%)	Dermatophytes	Spot treatment
Polyenes			
Amphotericin B	Fungizone ^g Cream, lotion, ointment (3%)	<i>Candida</i>	Limited use as irrigant for affected mucosal tissues
Nystatin	Mycostatin ^c Ointment, cream, or powder (10 ⁵ µg); suspension (10 ⁵ U/ml); tablets 5 × 10 ⁵ U	<i>Candida</i> dermatophytes, variable <i>Aspergillus</i>	Limited as irrigant for affected mucosal tissues
Imidazoles			
Thiabendazole	Solution (13%)	Dermatophytes, <i>Candida</i> , <i>Aspergillus</i>	Third choice for nasal aspergillosis
Ketoconazole	Nizoral ^h Cream, shampoo, solution (2%)	Dermatophytes, <i>Malassezia</i>	Poor efficacy in dermatophytosis
Econazole nitrate	Spectazole, ⁱ Sebazol Cream, spray, powder (1%)	Dermatophytes, <i>Candida</i>	Spot treatment, may need to treat whole animal
Miconazole nitrate	Micatin ⁱ Powder, shampoo, cream, lotion (2%)	Dermatophytes, <i>Candida</i> , <i>Malassezia</i> , <i>Leishmania</i>	Spot treatment, shampoo efficacy undocumented
Clotrimazole	Lotrimin, Mycelex ^c	Dermatophytes, <i>Candida</i> , <i>Aspergillus</i>	First choice for nasal aspergillosis, urinary flush for resistant candidal urinary infection
Enilconazole	Cream, lotion, solution (1%) Imaverol ^h Solution (10%)	Dermatophytes, <i>Aspergillus</i>	Second choice for canine nasal aspergillosis, toxic to cats

Nystatin is a polyene antibiotic that is closely related to AMB and produced by *Streptomyces noursei*. It is poorly absorbed after oral administration or topical application to skin or mucous membranes. Because it is very toxic to internal tissues, parenteral administration must be avoided. Although nystatin is somewhat effective against dermatophytes and *Aspergillus* species, its primary use has been to treat candidiasis. Liposomal nystatin has lower toxicity than the conventional preparation; however, the in vitro and experimental in vivo efficacy has not been superior to AMB.¹²⁶

Although azole derivatives were discussed in the systemic antifungal drugs section, several agents are only used topically. *Thiabendazole* (13%) has been used as a dip 3 times weekly for 3 weeks to treat cats with dermatophytosis. *Miconazole* was initially licensed for systemic use, but it is no longer used in this way because of its toxicity. Miconazole is now used topically in a variety of veterinary preparations for dermatophyte or yeast infections of the skin or ears. Polymyxin B, included in some of these preparations to treat bacteria, and miconazole may have a synergistic effect against bacteria and fungi. Shampoos containing miconazole and chlorhexidine are available for topical treatment of cutaneous fungal infections. Miconazole has often been used as a topical treatment for dermatophytosis in conjunction with simultaneous systemic therapy with griseofulvin. *Clotrimazole* is very effective against yeasts, dermatophytes, and *Aspergillus* species. Because of its limited absorption, severe irritation of the GI tract, and systemic toxicity, it has been confined to topical application, especially for treatment of dermatophytosis (see [Chapter 58](#)) and nasal aspergillosis (see [Chapter 65](#) and Drug Formulary, [Appendix 8](#)).²⁰ It was more effective than miconazole in treating dermatophytosis in dogs and cats when applied as a 1% solution twice daily for 2 weeks. Clotrimazole has also been instilled in the urinary bladder to treat *Candida* species cystitis in dogs and cats^{34,134} (see [Chapter 65](#)). *Enilconazole* is a topically applied derivative that has been valuable in the treatment of nasal aspergillosis (see [Chapter 64](#) and Drug Formulary, [Appendix 8](#)). Several other topical azole preparations from human medicine are listed in [Table 57-4](#).

⁵⁸CHAPTER 58 Cutaneous Fungal Infections

58.1 DERMATOPHYTOSIS

Douglas J. DeBoer

Karen A. Moriello

58.1.1 Etiology

58.1.1.1 Pathogenic Dermatophytes

Dermatophytosis is a superficial cutaneous infection with one of a group of keratinophilic fungi. The great majority of canine and feline dermatophyte infections worldwide are caused by *Microsporum canis*, *Trichophyton mentagrophytes*, or the geophilic species *Microsporum gypseum*,^{38,124} although the list of species of dermatophytes that have been reported occasionally or rarely from symptomatic or asymptomatic dogs and cats is extensive (Table 58-1). The prevalence of infections caused by each of the three common etiologic agents varies geographically. In cats, over 90% of infections are caused by *M. canis* worldwide. The prevalence of *M. gypseum* infection, which is most common in humid tropic and subtropic areas, varies seasonally, being more common in summer and autumn.¹²⁴ Simultaneous infection of dogs with more than one dermatophyte species may occur. Of combined infections, those caused by *M. gypseum* and *T. mentagrophytes* have been the most common.

Phenotypic¹²⁸ and genotypic^{88,111} diversity within different strains of the same dermatophyte species is now widely recognized. Various DNA fingerprinting techniques have demonstrated strain variability within species such as *M. canis* and *T. mentagrophytes* and have also led to potential reclassification of some of the minor *Microsporum* spp.^{88,111,116} The practical importance and clinical implications of this variation are as yet uncertain.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 58-1 Dermatophyte Species Reported from Specimens from Dogs and Cats

SPECIES	HOSTS	GEOGRAPHIC RANGE/COMMENT
Zoophilic		
<i>Microsporum canis</i> ^a (includes <i>M. distortum</i>)	B	Worldwide; common
<i>M. equinum</i> (horses; resembles <i>M. canis</i>)	D	?; rare
<i>M. nanum</i> (pigs)	B	Worldwide
<i>M. gallinae</i>	B	Worldwide
<i>Trichophyton equinum</i> (horses)	B	Worldwide
<i>T. verrucosum</i> (cattle, sheep)	B	Worldwide
Sylvatic		
<i>T. mentagrophytes</i> includes <i>T. mentagrophytes erinacei</i> (hedgehogs) and <i>T. mentagrophytes quinckeanum</i> (mice)	B	Worldwide; common
<i>M. persicolor</i> (voles)	B	Europe and Canada; not in hair
Geophilic		
<i>M. cookei</i>	B	Worldwide
<i>M. fulvum</i> (resembles <i>M. gypseum</i>)	B	Worldwide
<i>M. vanbreuseghemii</i> ^a	B	Eurasia and North America
<i>T. simii</i>	B	India; frequently infects monkeys and poultry
<i>M. gypseum</i>	B	Worldwide; especially warm climates; common
<i>T. terrestre</i>	B	Worldwide; not very pathogenic; not in hair
<i>T. ajelloi</i>	B	Worldwide; not very pathogenic; not in hair
Anthropophilic		
<i>Epidermophyton floccosum</i>	B	Worldwide
<i>M. audouinii</i> ^a	B	Worldwide
<i>T. megninii</i>	B	Africa, Europe
<i>T. rubrum</i>	B	Worldwide
<i>T. schoenleinii</i>	B	Africa, Asia; rare in Americas
<i>T. tonsurans</i>	B	Worldwide; especially Latin America
<i>T. violaceum</i>	B	Worldwide; rare in North America

58.1.1.2 Fungal Microflora on the Hair and Skin

Dogs and cats harbor many saprophytic molds and yeasts on their haircoats and probably on dermatitic skin as well. The most common fungi isolated from the haircoats of clinically healthy cats are *Alternaria*, *Aspergillus*, *Cladosporium*, *Penicillium*, *Rhizopus*, and *Trichoderma*.^{162,163,171} From dogs, the same fungi are isolated with somewhat different frequencies.¹⁸⁹

At one time, it was proposed that cats are reservoirs of pathogenic dermatophytes (*M. canis*, *M. gypseum*, *Microsporum vanbreuseghemii*, *Trichophyton verrucosum*, *T. mentagrophytes*, *Trichophyton rubrum*, *Epidermophyton* spp.). To investigate this possibility, many populations of cats have been surveyed by culture.^{79,153,189,203} Using similar techniques, fungal isolates from the haircoats of pet, stray, or cattery cats

Infectious Diseases of the Dog and Cat, 3rd Edition

from various geographic regions were collected. The prevalence of dermatophyte isolation, specifically *M. canis*, varied among the populations, depending on the geographic region, whether or not the cat was a stray or pet cat, and the presence or absence of skin disease at the time of sampling. *M. canis* was most commonly isolated from stray cats or those in multiple cat facilities and from warm geographic regions.

In surveys of pet cats from the United States, Belgium, and the United Kingdom, the prevalence of *M. canis* isolation in 172 cats was 0%, in 467 was 2.1% and in 181 cats was 2.2%.¹⁵³ In the last study, all four of the cats with positive culture results were from multiple-cat households and were allowed to roam freely outside. Interestingly, in the United States study, *T. rubrum* was isolated from 14 cats; this organism is the human pathogen associated with tinea pedis (athlete's foot).⁷⁹ This point highlights the importance of fomite carriage by the haircoat of dogs and cats of potentially pathogenic dermatophytes; *T. rubrum* infection is rare in cats.

In catteries, the isolation of *M. canis* depends greatly on whether the cattery has a history of dermatophytosis. In one study of catteries from temperate regions of the United States, cats had either negative culture results, or, in *M. canis*-affected catteries, virtually all cats had positive culture results.¹⁶³ These findings were identical to those of a smaller study from a warmer region of the United States that also failed to isolate *M. canis* from the haircoat of cattery cats from facilities that were free of the disease.²²⁴

In surveys of stray and shelter cats, the incidence of *M. canis* isolation was higher. In the United States, the isolation of *M. canis* from animal shelters in a subtropic climate was 17.5% compared with 4% from a temperate climate.¹⁷¹ Both isolations were performed at the same time of the year. In a study conducted in Belgium, 134 cats were cultured and *M. canis* was isolated from 15.7%.¹⁵³ A study from Italy emphasizes the impact that climate and geography has on the prevalence of *M. canis* isolation.²⁰³ In this study, 173 stray cats without skin disease were sampled, and 47% had positive culture results for *M. canis*. These studies on the fungal flora of dogs and cats highlight two important points. First, pathogenic dermatophytic fungi (e.g., *M. canis*) should not be considered part of the normal fungal flora of cats (or dogs). If they were, they would have been isolated routinely from healthy dogs and cats regardless of geographic region, lifestyle (indoor or outdoor), or status (pet or stray). Second, isolating pathogens from clinically healthy animals is possible. The isolation of a pathogenic organism indicates either infection (obvious or subclinical) or fomite carriage from exposure to a contaminated environment. However, if the animal is lesion free, distinguishing between these possibilities is often impossible. Regardless, animals with positive culture results should be treated because dermatophytosis is an important zoonotic disease.

58.1.2 Epidemiology

The exact prevalence of dermatophytosis is unknown because the disease is not reportable, even though it is a zoonosis. In clinical practice, dermatophytosis is overdiagnosed, most likely because of its similarities to other skin diseases. In all studies of skin disease of dogs and cats in which fungal cultures have been performed, the prevalence of dermatophyte infections seems to be approximately 2% of all dermatologic cases. The percentage of positive culture results among specimens submitted from suspected ringworm cases has ranged from less than 4% to 50%.^{28,124,134,214} In the United Kingdom, a survey showed that culture results were positive from only 16% of 8349 specimens from dogs or cats suspected of having dermatophytosis, whereas in Turin, Italy, the figure was 40% of cases examined.^{134,214} These figures may reflect not only geographic variation, but also differences in the types of cases chosen for dermatophyte culture. Environmental factors, such as increased warmth and high humidity, and animal background, such as existence of debilitation or concurrent disease,

Infectious Diseases of the Dog and Cat, 3rd Edition

extremes of age, feral behavior, or congregated housing, may increase the prevalence of infection in dogs and cats.⁴ Long haircoats, especially in cats, may predispose the animal to infection because the hair may become matted or protect the spores from removal by grooming and increase contact with the underlying skin.⁴

58.1.3 Pathogenesis

58.1.3.1 Transmission and Predisposing Factors

Dermatophytes are spread between animals or to persons from animals by direct contact, by contact with infected hair and scale in the environment, or via fomites. The typical infective portion of the organism is the arthrospores, formed from the segmentation and fragmentation of fungal hyphae. These infective spores are small and can be carried on air currents and dust particles or fomites. Fleas from infected animals can also transmit the disease. The dose or quantity of infective material needed to establish spontaneous infection is unknown; under experimental conditions, at least 100 spores typically are required. Infections have been traced to contact with contaminated brushes, collars, environments, and casual contact with subclinically infected cats. Casual contact is of particular concern for individuals working in multiple-animal facilities because not many infected hairs are needed to transmit the infection. Transmission to a child from the interior of a used car was reported.²²⁵

After reaching the haircoat, infective spores must compete with natural host defense mechanisms to establish infection. Under optimal conditions of temperature (25° C to 37° C), infective spores can germinate within 6 hours of adherence to keratinocytes. Arthrospores adhere very strongly to keratin. Arthrospores cannot penetrate healthy intact skin; some type of superficial trauma is needed to facilitate infection. The amount of trauma required is relatively minimal based on experimental models of infection.⁵⁵ Increased hydration and maceration of the skin (e.g., within footwear) is a common predisposing factor to infection in people. Moisture enhances the ability of dermatophytes to penetrate the skin and favors germination. In general, the normally dry condition of the skin surface and fungistatic properties of serum and sebum are natural host defense mechanisms. Normal grooming behavior of cats distributes sebum from areas of high concentration and production (chin and dorsum) to other areas of the body and may remove spores.

The incubation period is 1 to 3 weeks. With *M. canis* infections, the source is typically an infected cat or fomites contaminated by cats. In contrast, most *Trichophyton* infections are suspected of being caused by contact with rodents or their nests. *M. gypseum* is a geophilic organism that inhabits rich soil; dogs and cats are exposed by digging and rooting in contaminated areas. Infections with anthropophilic species are acquired, albeit uncommonly, as *reverse zoonoses* by direct contact with infected persons.

Dermatophytosis is more common in hot, humid environments, which may contribute to conditions favoring outbreaks of dermatophytosis in multiple-animal facilities. Excessive bathing and grooming of cats or dogs may predispose them to infection by removing normal host defense mechanisms (fungistatic sebum and serum), removal of epidermal cells that act as an intact barrier, and increasing the humidity of the skin and haircoat. In addition, routine sanitation in multiple-cat facilities may also increase humidity, favoring development of infection.

Dermatophyte infections of dogs and cats involve the hair shaft, follicle, and surrounding stratum corneum. Infected hair shafts are fragile, and dislodged hair fragments containing infective spores are the most efficient means of transmission to other hosts. Such material may remain infectious in the environment for

Infectious Diseases of the Dog and Cat, 3rd Edition

many months. One study found that samples of hair stored for 18 months could yield positive culture results.²²¹

58.1.3.2 Virulence Factors

Several different proteolytic enzymes (keratinase, elastase, and collagenase) have been isolated from dermatophyte fungi, and a role for these proteases has been proposed in the initiation and progression of infection.^{1,29,30,69} The enzymes are produced under in vitro culture conditions, as well as being detectable in infected skin biopsies.¹⁵⁴ The number and quantity of enzymes produced varies from strain to strain and may, in part, explain variability in clinical presentation.¹

58.1.3.3 Immunology

When infective dermatophyte arthrospores contact the hair and skin, many factors influence whether infection will ensue. Some of these factors are not dependent on development of a specific immune response to the fungus. Trauma facilitates development of infection. Normal serum inhibits growth of dermatophytes, as do fungistatic fatty acids present in sebum. Physical occlusion leads to increased hydration of the normally dry skin surface, with subsequent maceration and easier infection. The overall immunologic status of the host influences development of infections. Infections are more easily established in very young, very old, or immunocompromised animals and people. For example, an increased frequency of isolation of *M. canis* was

552

553

reported in feline immunodeficiency virus–infected cats.¹²⁹ These innate factors in *resistance* are distinct from the specific immunologic responses acquired as a consequence of infection.

58.1.3.3.1 Dermatophyte Antigens

Three different physical components of dermatophytic fungi have received the most attention for their role as antigens in the host immune response: cell wall carbohydrates, cell wall proteins, and secreted keratinases. Fungal mycelium is composed of approximately 10% protein, 20% carbohydrate (notably chitin and mannan), and 70% lipid. The immunologically active portion of the cell wall is of glycopeptide composition, with the carbohydrate portion chiefly involved in immediate-type hypersensitivity and the peptide portion important in delayed-type hypersensitivity. These glycopeptides are not fungal species specific; abundant cross-reactivity is present across different genera of keratinophilic fungi. Most infected individuals also develop humoral and cell-mediated immunity (CMI) against fungal keratinases, proteolytic enzymes secreted at the tips of the invading hyphae. Fungal keratinases, including those from *M. canis* of feline origin, have been isolated and characterized chemically and immunologically.^{150–152} Antibodies developed against dermatophyte antigens cross-react with mycelial antigens from common saprophytic fungi such as *Penicillium*, *Hormodendrum*, *Aspergillus*, and so forth, and attempts to classify dermatophytes according to serologic reactivity were not successful.

58.1.3.3.2 Acquired Immunity During Infection

Though the host immune response to dermatophyte infection has been the subject of investigation for nearly a century, only relatively recently has the immunology of this disease been closely studied in companion animal species, and most information comes from studies performed in cats. Overall, early animal studies generally concluded that CMI, rather than humoral immunity, is more important in resistance to reinfection. The majority of human patients with acquired dermatophytosis develop positive

Infectious Diseases of the Dog and Cat, 3rd Edition

intradermal test (IDT) reactions to dermatophyte antigens. Development of a delayed (48 to 72 hours) IDT reaction represents CMI and correlates well with both a positive lymphocyte blastogenesis test result and at least partial immunity to reinfection. Development of an immediate (15 to 30 minute) IDT reaction represents development of reagenic antibody-mediated hypersensitivity. Attempts have been made to relate the type of positive skin test reaction (immediate or delayed) to clinical status of the patient. As a general rule, human patients who recover from acute dermatophyte infections develop positive delayed IDT reactions and usually are relatively immune to further infection. In contrast, some human patients develop chronic, unrelenting dermatophytosis that persists for months or years. These patients develop strong immediate IDT reactions but often fail to exhibit delayed reactions even after prolonged disease. This evidence led to early speculation that a strong cell-mediated, delayed-type hypersensitivity response is responsible for elimination of the infection, whereas an immediate-type, antibody-mediated hypersensitivity response tends to inhibit or delay recovery.⁹⁹

Natural infection of cats with *M. canis* is accompanied by both a humoral antibody response (rising immunoglobulin G [IgG] titers, and sometimes positive immediate IDT result) and a cell-mediated response (positive lymphocyte blastogenesis and delayed IDT results) against dermatophyte components, including glycoprotein extracts.^{54,56,168} Available data suggest that these responses are not completely *Microsporum*-specific; that is, cross-reaction is present with *Trichophyton*. Delayed IDT reactions are often weaker in cats with active infections and in cats whose infection was aborted with antifungal treatment, suggesting that the infection must run its entire natural course for development of full immunity.¹⁶⁸ Both IDT and in vitro data in cats supports the concept that recovery from dermatophytosis depends on development of a strong CMI response.

Genetic factors also influence the development of chronic dermatophytosis in people, as evidenced by the higher prevalence of chronic infections among related individuals versus unrelated individuals living in the same household. Genetic factors may be important in cats as well. In one cattery study, chronic dermatophytosis was found most commonly in three facilities where the cats were genetically related.¹⁶³ Cats with chronic dermatophytosis had significantly higher antidermatophyte antibody levels and different lymphocyte blastogenic responses.

Once an individual recovers from dermatophytosis, generally, at least partial immunity to reinfection is present. This resistance varies in degree and duration, depending on the individual, host species, strain of dermatophyte, and the site of the original infection. Resistance is often observed to be generalized (the whole body) but typically is greatest at or near the previously infected site. Resistance is relative: experimentally inducing a second infection in a recovered person or animal is generally possible, but it requires a much greater number of spores or more occlusive conditions, or both. Additionally, the subsequent infections are cleared sooner than the first. Maximal resistance may take two or more episodes of infection to develop.

58.1.4 Clinical Findings

Dermatophytosis is a pleomorphic disease and cannot be diagnosed based on clinical signs alone. Dermatophytosis is primarily a follicular disease, and the most common clinical signs include hair loss, scaling, and crusting. Pruritus is variable. Some patients may develop a classic ringlike lesion with central healing and fine follicular papules on the periphery. Generally, however, signs and symptoms are highly variable and depend on the degree of inflammation and hair shaft destruction ([Table 58-2](#)).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 58-2 Diverse Clinical Features of Dermatophytosis

Cats	Alopecia, frayed hairs
	Pruritus
	Erythema
	Scaling and crusting
	Comedones (feline acne)
	Hyperpigmentation
	Paronychia
	Pruritic ear pinnae (<i>M. canis</i>)
	Miliary dermatitis (one cause)
	Granulomatous nodules or ulcers
	Facial fold pyoderma, conjunctivitis
Dogs	Alopecia
	Papules or pustules
	Crusts, scales, hyperpigmentation
	Facial furunculosis
	Nodular skin lesions (kerion reactions)
	Onychomycosis
	Urticaria and papular eruptions

553

58.1.4.1

Cat

554

Dermatophytosis can seemingly mimic almost any described feline skin disease. *M. canis* infection is not generally a localized disease, despite appearances to the contrary. Clinical lesions may be focal or multifocal, but spores or areas of inapparent infection, or both, will be present throughout the haircoat. Pruritus varies from none to self-mutilation. Hyperpigmentation of the skin is rare in cats but is most likely seen in cats with dermatophytosis. Scaling may be limited or generalized and diffuse or multifocal. Because hair loss is a common finding, a usual owner complaint is excessive shedding. Cats with generalized dermatophytosis often ingest large amounts of hair while grooming and may have a history of vomiting, constipation, hairball problems, or any combination of these. Erythema and scaling of the inner or outer pinnae (or both) is another common presentation in adult cats. Patches of scale with minor alopecia or hair breakage is one of the most common presentations in longhaired cats. Feline skin reaction patterns where dermatophytosis should be considered as a differential diagnosis include miliary dermatitis, symmetrical alopecia, eosinophilic plaques, and indolent ulcers.

Dermatophyte lesions in kittens tend to consist of areas of hair loss and scaling; erythema is variable and is often difficult to detect in dark-haired cats. Lesions are often first seen as areas of hair loss on the muzzle, face, ears, and forelegs (Fig. 58-1). Depending on the overall health of the kitten, lesions may be focal, multifocal, or generalized. Kittens with limited dermatophyte lesions that develop upper respiratory infections or gastrointestinal (GI) diseases, or both, are at increased risk for the development of generalized lesions. *M. canis* can cause comedone-like lesions (i.e., *chin acne*) in young cats.

Uncommon presentations of feline dermatophytosis include an appearance clinically identical to pemphigus foliaceus, with scaling and crusting over the bridge of the nose and the face or crusting exudative paronychia, or both. Unilateral or bilateral pinnal pruritus is another under-recognized presentation of *M. canis*. In the cats examined by the author (KAM), infected hairs were limited to the ear margin or long hairs within the “bell” of the ear, or both. *M. canis* is uncommonly a cause of recurrent otitis externa.⁸⁹ Rarely, diffuse alopecia with hyperpigmented patches of long hair has been observed.²⁰⁰

Fig 58-1 Dermatophytosis in this kitten with *M. canis* is characterized by patchy alopecia with marked scaling and hyperkeratosis. (Courtesy University of Wisconsin Teaching Materials, University of Wisconsin, Madison, Wisc.)

Granulomatous dermatitis, in the form of well-circumscribed, ulcerated dermal nodules, is infrequently recognized in cats (Fig. 58-2). The lesions occur on cats afflicted with more generalized typical *M. canis* infections. Interestingly, one report described different strains of *M. canis* isolated from the granulomatous lesions and from the surface infections of the same cat.¹⁵⁵ These lesions have been called mycetomas, pseudomycetomas, and Majocchi's granulomas. This form of disease carries a poor prognosis for resolution.²⁰¹

58.1.4.2

Dog

Lesions in puppies usually consist of focal or multifocal areas of hair loss and are clinically indistinguishable from other common causes of focal hair loss in a puppy, specifically demodicosis and bacterial pyoderma. As in kittens, the overall health of the puppy is an important factor in the severity of the infection.

Unlike cats, dogs are more likely to develop the *classic* foci of alopecia with follicular papules, scales and crusts, and a central area of hyperpigmentation (see Table 58-2). Dermatophytosis should be considered in any papular or pustular eruption. Facial folliculitis and furunculosis, superficially mimicking an autoimmune skin disease, can develop (Fig. 58-3). Nodular skin lesions called *kerion reactions* may occur on the face and legs (Fig. 58-4). These lesions appear as areas of deep pyoderma and are most often caused by *M. gypsum*

Infectious Diseases of the Dog and Cat, 3rd Edition

or *Trichophyton* spp. infections. More generalized, widespread lesions should prompt a search for a potential underlying systemic cause predisposing to the infection.^{39a} Onychomycosis may be exhibited by chronic unguinal fold inflammation, with or without footpad involvement, or the claw alone may be infected, which causes claw deformity and fragility. Dermatophytic granulomas have been reported rarely in dogs.⁷ One of the authors (DJD) has seen several shorthaired dogs with histories of recurrent urticaria and papular eruptions caused by dermatophytosis.

554

555

Fig 58-2 Granulomatous dermatitis has developed in this cat with generalized dermatophyte infection caused by *M. canis*. Microscopically, this lesion resembled a mycetoma. (Courtesy Gail Kunkle, University of Florida, Gainesville, Fla.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 58-3 Facial folliculitis and furunculosis in this dog was caused by *T. mentagrophytes*. This dog was referred as a suspected pemphigus foliaceus case. (Courtesy University of Wisconsin Teaching Materials, University of Wisconsin, Madison, Wisc.)

Fig 58-4 This nodular skin lesion on a dog is a kerion caused by *M. gypseum*. (Courtesy University of Wisconsin Teaching Materials, University of Wisconsin, Madison, Wisc.)

Demodicosis and dermatophytosis can be clinically indistinguishable but can be reliably differentiated by a skin scraping. Superficial folliculitis, especially when accompanied by the spreading rings of erythema and exfoliation that have been characterized as *staphylococcal hypersensitivity* or *superficial spreading pyoderma*, is more often mistaken for dermatophytosis. Staphylococcal skin lesions of seborrheic spaniels are also often misdiagnosed as dermatophytosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

58.1.5 Diagnosis

Although some research has focused on cellular and humoral responses to dermatophyte infections,^{56,63,217,219} only preliminary work has been reported on serologic diagnosis of canine dermatophytosis.^{194,81a,184a} Followup studies examining cross-reacting antibodies in experimental and naturally occurring feline dermatophytosis are needed because serology might be a useful tool for protecting cat breeders from importing infected animals to their facilities. Additionally, investigating the appropriateness of the immune response to infection in groups of persistently infected animals may soon become possible.²¹⁸ Other new developments in diagnosis include the production of polymerase chain reaction probes and immunohistochemical stains for the various species of dermatophytes.¹ Such techniques promise more rapid identification in clinical specimens but have yet to be developed for commercial use. Calcofluor white has been mentioned to improve the diagnostic accuracy of direct microscopic examination of hairs (see following discussion).²²⁰

Fig 58-5 Wood's light examination of a cat with dermatophytosis showing positive fluorescence results. (Courtesy Jeanne Barsanti, University of Georgia, Athens, Ga.)

58.1.5.1 Wood's Light Examination

Examination of the haircoat with a Wood's (ultraviolet, 320 to 400 nm wavelength, light) lamp is a quick and easy initial screen for presence of certain dermatophyte infections but clearly is not definitive. Perhaps only one half of all strains of *M. canis* will show fluorescence and other animal dermatophyte species will not, rendering the Wood's lamp an insensitive test. The fluorescence results from a fungal metabolite produced only when the organism is growing on hair and not on scale or claw material. Thus true fluorescence is bright "apple green" in color and occurs only along hair shafts, never in scale (Fig. 58-5). Debris, scale, lint, and topical medications commonly produce false fluorescence. Because of these pitfalls, suspected fluorescing hairs should always be cultured or examined microscopically, or both, to confirm presence of the

Infectious Diseases of the Dog and Cat, 3rd Edition

infection. Compared with culture, the Wood's lamp examination was found to have a sensitivity of approximately 50% for *M. canis* infection.²¹⁴ Wood's lamp examination is most useful when monitoring infection status in a cattery or multiple-animal facility where endemic infection with a fluorescing strain is involved. In examining a patient with a Wood's lamp, make sure that the lamp has been allowed to warm up for a few minutes before the examination, and spend several minutes (with room lights out) examining the haircoat slowly and closely both to allow sufficient time for dark-adaptation and to avoid missing small areas of fluorescence.¹⁶⁶ The authors find that the larger, more powerful lamps that operate on household current are superior to smaller, battery-operated models.

* References: 9, 87, 88, 111, 125, 192, 226.

58.1.5.2

Direct Microscopic Examination

Mineral oil is often used to remove and suspend hairs for microscopic evaluation. However, the hair shafts are opaque reducing visualization of the fungal elements. Hair and scale may be wet mounted in 10% to 20% potassium hydroxide (KOH) overnight or heated gently in the same solution for 10 minutes for clearing of keratin and visualization of fungal elements. Mounting in chlorphenolac (50 g chloral hydrate, 25 ml liquid phenol, and 25 ml liquid lactic acid) solution accomplishes the same task in a few minutes without heating, but the solution is not commercially available and is cumbersome to prepare. Even in experienced hands, direct examination is time consuming and may be diagnostic in only a few cases. It may lead to misinterpretation if saprophytic fungal spores are present in the specimen; debris and the complex structure of normal hair shafts can be misinterpreted as fungal elements. Dermatophytes never form macroconidia in tissue, but rather form hyphae and arthroconidia (*ectothrix* spores) on hair and scale. One investigation has recommended hair examination with a solution of 0.5 % calcofluor white stain (Beckton Dickenson, Franklin Lakes, N.J.) and Evans blue dye (1:9 solution) in equal volume of 20% KOH for superior visualization of fungal elements.²²⁰ Direct microscopic examination is most useful when fluorescing hairs are found and can be directly plucked with a forceps under a Wood's lamp. The Wood's lamp can be used as a light source for the microscope to aid in visualization. In this case, the finding of ectothrix spores along the hair or mycelium, or both, growing down the center of the hair shaft (Fig. 58-6, A and B) is justification for beginning treatment while awaiting more definitive culture identification of the pathogen. Compared with normal hairs, infected ones are thicker, frayed, and indistinct with a filamentous appearance.

555

556

Fig 58-6 A, Microscopic appearance of infected hairs cleared with KOH. The lower hair (A) is normal; note the upper hair (B) is swollen, misshapen, and has tiny spherical ectothrix spores on the surface (unstained, $\times 100$). B, This KOH-digested microscopic preparation of hair and scale from a dog contains a multiloculated fungal spore that may be mistaken for a dermatophyte macroconidium. It is an *Alternaria* spore. Dermatophytes never produce macroconidia in tissue. C, Microscopic appearance of macroconidia (arrow) from a positive dermatophyte test medium culture, displaying typical morphology for *M. canis* (unstained, $\times 100$). Infectious Diseases of the Dog and Cat, 3rd Edition

58.1.5.3 Fungal Culture

Definitive diagnosis of dermatophytosis is made by culture, although it is neither perfectly sensitive nor always specific for the diagnosis.²¹⁴ Proper specimen collection techniques, regular examination of the growing cultures, and microscopic confirmation of the fungal species are all necessary for ideal performance of this test.

556

58.1.5.3.1 Specimen Collection

557

Specimens can be taken either by plucking hair and scale from suspected lesions or by using a brushing method; the latter method is highly recommended. If hairs are to be plucked, the area should be patted clean with an alcohol-moistened gauze and then allowed to dry. Hair shafts should be collected from several suspect sites by pulling them with a forceps or hemostat. Hairs that appear broken and near active inflammation should be selected. Scales should be included in the sample. Exudate or antiseptics should not be transferred to the medium. Brushing techniques have become favored in recent years because they allow sampling of much larger areas of the haircoat simultaneously such that the chance of missing an active area of infection is less. For this method, a new inexpensive human toothbrush is vigorously combed over regions of suspected infection (or, alternatively, all parts of the haircoat) for 2 to 3 minutes. These brushes are mycologically sterile in their original wrapping and need not be sterilized. Hairs should be visible in the bristles after brushing. The bristles and attached hairs are then pressed lightly and repeatedly (20 to 30 times) onto the surface of the culture medium, attempting to ensure contact of all sides of the sampling brush with the medium. Leaving collected hairs on top of the medium, or “planting” the hairs into the medium is unnecessary. Care must be taken not to press too firmly into the medium such that agar is removed with the brush. The toothbrush can be discarded after a single use. For followup cultures, owners can be taught to sample their pets at home, brushing the animals one at a time and depositing the brush into an individual, sealed plastic bag marked with the pet's name. This procedure avoids having to transport potentially infected animals to a clinic, with contamination of the vehicle and veterinary premises. Note that the toothbrush method requires use of culture medium in a plate format, rather than in tubes or vials, because insertion of the brush to inoculate into a narrow tube or vial is mechanically impossible.

58.1.5.3.2 Special Specimen Collection Situations

The toothbrush method excels in identification of animals with mild, subclinical, or asymptomatic infections. In this case, every square inch of the entire animal—from nose to tail, including limbs and all trunkal surfaces—is sampled by vigorous brushing for several minutes, and the medium is inoculated as previously detailed. In kittens, brushing the face and in the hairs on the inside of the *bell* of ear is important. Early lesions of dermatophytosis often start at these sites, and, unfortunately, these sites are often undersampled or not sampled at all during coat brushes.

When dermatophytosis is suspected as a cause of claw or nailbed infection, special culture techniques may be needed. In many cases, the hair surrounding the ungual fold may be infected and may be cultured, as is done elsewhere on the body. However, in dogs, geophilic fungi may contaminate preexisting foot lesions; thus correlating cultural findings with histologic demonstration of fungi in hair or claw may be necessary. Otherwise, repeated isolation of fungus from the lesions may be regarded as evidence of causation. If the

Infectious Diseases of the Dog and Cat, 3rd Edition

claws alone are affected, a scalpel blade may be used to shave fine pieces from the proximal end of clipped or surgically excised specimens for culture.

Table 58-3 Comparison of Dermatophytes Isolated from Dogs or Cats

ORGANISM	COLONY CHARACTERISTICS	MICROSCOPIC APPEARANCE
<i>Microsporum canis</i>	White top surface, yellow-orange reverse pigment undersurface; flat with depressed center; cotton or wool consistency	Macroconidia: spindle or canoe shaped; each contains ≥ 6 cells with thick walls with outer spines on surface and terminal knob
<i>Microsporum gypseum</i>	Cinnamon brown top surface, yellow to tan reverse pigment undersurface; flat colonies; face powder consistency	Macroconidia: row-boat shaped; each contains < 6 cells with thin walls Microconidia: single cell
<i>Trichophyton</i> spp.	White to cream top surface, tan to brown to red reverse pigment under surface	Macroconidia: rare; cigar shaped Microconidia: common; often spiral hyphae

If surgical biopsy is performed on nodular lesions, aseptically collected and transported tissue should be submitted for cultural and histologic examination.

58.1.5.3.3

Media, Incubation, and Interpretation

Culture can readily be performed as an in-office procedure employing dermatophyte test medium (DTM). DTM consists of a nutrient medium plus inhibitors of bacterial and saprophytic growth and phenol red as a pH indicator. Several variants are available, some of which claim to speed growth of the culture, but all perform similarly.^{71,95} DTM is sold in either vials or plates; the latter are preferable because they permit inoculation with a toothbrush. For incubation, DTM containers should be loosely covered or capped at room temperature and protected from ultraviolet light and desiccation, for example, in a covered container containing a damp paper towel. Dermatophyte colonies may appear as soon as 5 to 7 days after inoculation, but the culture plates should be retained for 3 weeks before calling the culture result negative. Plates should be inspected daily for a color change of the medium to red and growth of a white to buff colored, powdery to cottony mycelium. The color change must occur *at the same time* the colony is first visible, never later. All fungal growth, including nonpathogens, will produce a red color change after the colony has grown for several days to a week. Dermatophyte colonies are never green, gray, brown, or black.

Dysgonic varieties of *M. canis* (sometimes called *M. canis* var. *distortum*) may occasionally be isolated, particularly from cat colonies.^{188,206} These varieties grow under the surface of the agar, giving a feathery or snowflakelike appearance. They do not produce conidia or a red color change on DTM¹⁶⁶ and can be converted to more typical forms by a diagnostic laboratory for identification.¹⁴⁰ Plates should be kept for 21 days, especially in monitoring treated animals, because fewer viable fungal spores will be present and their growth rate is often reduced.

Most often, large numbers of colonies of the dermatophyte will appear on the plate if the animal is truly infected. Table 58-3 describes the appearance of the most common isolates. The number of colonies decreases as the infection resolves spontaneously or from treatment. In some cases, only one or a few dermatophyte colonies appear. In addition to recovery, this finding may indicate either early or mild infection or poor sampling technique. This result can also be seen in uninfected cats that are living in the

557

558

Infectious Diseases of the Dog and Cat, 3rd Edition

same environment as are infected cats; in this case, the cat's coat has become contaminated with spores from the environment (i.e., the cat is acting as a fomite). Such *innocent carrier* cats are impossible to distinguish from cats with a mild infection using culture alone, and if any question arises, the suspect cat should be treated.

One of the most common problems with in-house culturing is the lack of sporulation or growth, or both, of *M. canis* on DTM. Noting that growth will be slow in animals that are being treated is important. Additionally, a recent study challenges the common recommendation to *incubate at room temperature*. Increased sporulation was found when plates were incubated at higher temperatures (21° C to 23.8° C [70° F to 75° F]).⁹⁵ This finding has been confirmed in our laboratory.¹⁶¹ Ambient temperature in many veterinary clinics, especially during warm weather months when the air conditioning is being used, is well below this temperature. The current recommendation by the authors is to incubate cultures at higher temperatures.

58.1.5.3.4

Microscopic Confirmation

The principle of DTM is not perfect, and even an immediate red color change is not diagnostic. For example, colonies of the nonpathogen *Scopulariopsis* can appear grossly identical to those of dermatophyte colonies and cause an immediate red color change. Therefore suspect colonies must be examined microscopically to confirm presence of a pathogen. After 7 to 10 days of growth, most colonies will begin to produce spores, which will allow specific identification. To accomplish this task, brush a small strip of clear cellophane tape lightly over the colony surface to collect spores. Place the tape (sticky side down) onto a drop of lactophenol cotton blue stain on a microscope slide. Add another drop of stain on top of the tape, then coverslip and examine at 100× magnification. Among the many hyphal strands will be dermatophyte macroconidia (spores), which have typical shapes according to the species (see [Fig. 58-6, C](#); [Table 58-3](#); and [Chapter 56](#)). If spores are not visible, wait 4 to 7 days and try again; some colonies may not sporulate until they are quite old. A suspect colony that fails to produce spores or is difficult to identify, as is sometimes the case in *Trichophyton* species, should be sent to a qualified diagnostic laboratory.

Table 58-4 Treatment Recommendations for Dermatophytosis in Cats

CAT ENVIRONMENT/OWNER	THERAPEUTIC PROCEDURES
Infected cat:	Shorthaired with <5 lesions: clip focally with blunt metal scissors.
No zoonotic risks	If longhaired or more lesions: clip entire body.
Only cat in household or up to four other cats	Administer topical and systemic antifungals until 2–3 negative culture results.
	Culture starting 4 weeks after treatment initiated.
Exposed cat:	Obtain toothbrush culture (see text).
Housemate of infected cat	Clip <i>entire</i> haircoat of cats with positive culture results.
Member of infected cattery	Provide whole body topical therapy (6 times).
Show cat in contact	
Infected cat with public health risk:	Administer systemic antifungals.
Children in household	Culture starting 4 weeks after treatment initiated at weekly or biweekly intervals until three successive negative culture results.
Cosmetologist	
Immunosuppressed	
Human or animal health care worker	

Infectious Diseases of the Dog and Cat, 3rd Edition

58.1.5.4 Histopathologic Findings

Biopsy examination is not as sensitive as culture is in the diagnosis of dermatophytosis. When the significance of culture results is questioned, demonstration of the organism in biopsy specimens is more definitive. Histologic examination is most helpful in detecting the nodular forms of dermatophytosis (the kerion and granulomatous ringworm), especially because these lesions often have negative culture results. Shaved, clipped, or surgically excised specimens of claws may be submitted for histologic examination in cases of paronychia, onychorrhexis, or onychomadesis. If fungal organisms are present, they will be readily visible within the substance of the claw. When submitting such specimens to the pathology laboratory, indicate the suspicion of fungal disease so that special fungal stains may be performed if necessary.

58.1.6 Therapy

An important point to recognize is that, in an otherwise healthy animal, dermatophytosis is generally a self-curing disease, with full resolution following development of an appropriate CMI response. In dogs, localized lesions and even generalized *M. canis* or *M. gypseum* infections can resolve without treatment.^{58,142,165} Cats and kittens with seemingly localized disease can also self-cure, but infection can be prolonged (from at least 60 to 100 days). Positive culture results from cats do not prove that the dermatophyte is causing the clinical illness given that they can innocently harbor the organisms as a fomite, and the signs are variable, mimicking other diseases. Treatment is recommended nevertheless because it will accelerate resolution, thus minimizing the time course of the infection and minimizing the potential that it will spread to other animals or people. Wherever possible, curing the infection in the cat and decontaminating the environment is desirable. Systemic treatment is mandatory under certain circumstances such as recurrent or recalcitrant infection or with any immunocompromised state. See [Table 58-4](#) for treatment guidelines based on the health status and environment of affected cats. Drugs and dosage regimens are summarized in [Table 58-5](#).

Experimental infection studies have emphasized that the ideal treatment regimen is composed of three elements (topical, systemic, and environmental treatment), each of which has a somewhat different role. Topical therapy reduces contamination on the haircoat (and thus environmental contamination) and results in a faster mycologic cure than systemic therapy alone.²¹⁶ However, with the exception of lime-sulfur or enilconazole, topical therapy appears to do little to accelerate complete clinical resolution in the animal. Systemic therapy, in contrast, benefits the individual animal by reducing the number of weeks to complete cure. Environmental treatment also reduces the chances that the infection will spread to other animals or people in the same household.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 58-5 Drugs for Systemic Therapy of Dermatophytosis in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION ^c (WEEKS)
Griseofulvin					
Microsize ^d	B	25–50	PO	24 ^e	6–10
Ultramicrosize ^f	B	5–10	PO	24 ^e	6–10
Ketoconazole ^g	D	10	PO	24	4–8
Itraconazole ^g	D	5–10	PO	24	4–8
	C: daily therapy	10	PO	24	4–8, or until cured
	C: continuous/pulse	10	PO	24	4 then every other week, until cured (~8–10 weeks)
	C: low-dose cycle	1.5–3	PO	24	Variable ⁱ
Terbinafine ^j	B	30–40	PO	24	3–18

B, Both dog and cat; D, dog; C, cat; PO, by mouth.

- a See Drug Formulary, [Appendix 8](#), for additional information on each drug.
- b Dose per administration at specified interval.
- c Followup brush culture results should be negative before discontinuing therapy. Two negative culture results are recommended.
- d Trade names: Grifulvin V, Fulvin U/F, Grisactin. For small kittens, usually culture negative at 8 weeks and cured at 10 weeks.
- e Dose can be divided and given every 12 hours. Dose of 50 mg/kg daily has often been effective after 41–70 days of therapy.
- f Dose is approximately two thirds that of microsize preparation. Some preparations contain polyethylene glycol to facilitate absorption. Trade names: Fulvicin P/G, Grisactin Ultra, Gris-PEG. Effective dosages are higher than manufacturer suggests and may be toxic. Note: manufacture of this drug may be discontinued.
- g Trade name: Nizoral; generic available; cats often receive 50 mg total dose daily; with side effects, every other day treatment is used. Not recommended for use in cats because of adverse effects: vomiting, inappetence.
- h Trade name: Sporanox (human). Capsules may be opened and contents divided to administer recommended doses, or use oral solution.
- i After 15 days, fungal culture is performed and cycle is repeated until negative culture result is obtained. Usually takes 1–3 cycles (15–45 days).
- j Trade name: Lamisil. Not yet evaluated in dogs. Monitor liver enzymes in cats. Can be substituted for itraconazole in various regimens.

58.1.6.1 Clipping of the Haircoat

Clipping of the haircoat will mechanically remove fragile hairs that will fracture and spill spores into the environment and onto the haircoat. It allows for thorough penetration of topical medications, reducing the amount and duration of treatment. Clipping of the entire haircoat is the optimal treatment in all cases of

Infectious Diseases of the Dog and Cat, 3rd Edition

dermatophytosis; however, this is not always possible or practical. Clipping is time consuming and often requires sedation and can be irritating to cats. The following guidelines are offered. Shorthaired animals with less than five focal lesions do not need to be clipped. Cats or dogs with long hair, more than five focal lesions, generalized lesions, concurrent skin or systemic illnesses, or any combination of these should have their entire haircoat clipped. Clipping of the entire haircoat with a #10 electric clipper blade is usually adequate in animals with generalized lesions. Clipping of the haircoat in catteries with dermatophytosis is helpful for successful eradication. Important to note is that clipping of the haircoat may temporarily exacerbate lesions; however, this should not be used as a reason to not clip the haircoat. The use of adequate sedation and a #10 blade will minimize skin trauma.

58.1.6.2

Topical Therapy

To date, no evidence has been found to support the use of localized or *spot treatment* for dermatophytosis in dogs or cats. In fact, evidence has been found suggesting that use of spot-treatment products alone may predispose individuals to chronic subclinical infections.²⁷ Rather, whole-body shampooing, dipping, or rinsing with topical antifungal agents is much preferred. General topical treatment recommendations are summarized in [Table 58-6](#).

Topical therapy, in addition to clipping of the haircoat, will help decrease contamination of the environment by hairs and spores, decrease the chance of spread of the disease to other animals and people, and help speed mycologic cure of the infection. The choice of topical antifungal treatment is important because studies have shown that many common topical agents are ineffective.² The relative efficacies of various topical antifungal drugs is summarized in [Table 58-7](#). In vitro and in vivo studies have shown that the most consistently effective topical antifungal whole body treatments are lime-sulfur, enilconazole, and miconazole (the latter with or without chlorhexidine).³ Captan, povidone-iodine, and chlorhexidine are consistently ineffective against *M. canis* and should not be used in lieu of the following products listed.

Lime-sulfur has been extensively tested in in vitro models, and when used at concentration of 8 ounces/gallon of water (1:16 dilution) has shown superior antifungal activity.^{79,170} Lime-sulfur used at 4 ounces/gallon has been ineffective in the treatment of cats with dermatophytosis in one of the author's experience (KAM). Lime-sulfur treatment alone, twice weekly at this concentration, has been used by one of the authors (KAM) to successfully treat dermatophytosis in single and multiple cat households when combined with whole body clipping and appropriate environmental treatment. Lime-sulfur is virtually nontoxic if applied properly and can be used even on newborn kittens and puppies.

Enilconazole topical solution is also an effective treatment; unfortunately, it is not available in the United States and is licensed only for use in dogs and horses. Because of its superior antifungal activity, the safety and efficacy of enilconazole have been evaluated in cats.^{96,103} In two studies, enilconazole was evaluated as a sole topical therapy (after whole body clipping) for the treatment of naturally occurring *M. canis* infection in Persian cats.^{67,103} In one study, cats were dipped with either water (control) or 0.2% (2 mg/ml) enilconazole twice weekly for 8 weeks.⁶⁷ In the enilconazole-treated cats, results of fungal cultures were negative as early as 5 weeks after initiation of therapy, and remained negative to the end of the 10-week monitoring period. In contrast, 75% of control cats still had culture-positive results at the end of 10 weeks of monitoring. In the second study, 22 Persian cats in a cattery were treated with 0.2% enilconazole every 3 days for a total of eight applications.¹⁰³ All cats improved clinically and had culture-negative results by day 28 of therapy. In both studies, cats were observed for adverse effects, and serum biochemistry panels were monitored. Enilconazole was well tolerated but may have been associated with hypersalivation, anorexia,

Infectious Diseases of the Dog and Cat, 3rd Edition

weight loss, emesis, idiopathic muscle weakness, and slightly elevated serum alanine aminotransferase concentrations. Anecdotal reports have surfaced of uncommonly severe toxicity, and even death, occurring in cats after topical application of enilconazole. These cases are thought to be associated with ingestion of the solution by the cat via grooming after application. Enilconazole appears safe for use on cats if the animals are fitted with an Elizabethan collar for a few hours after each treatment, to prevent grooming, until the cat is dry. See Drug Formulary, [Appendix 8](#), for further information.

Table 58-6 General Recommendations for Topical Antifungal Therapy

- The most consistently used antifungal topical agents are lime-sulfur, enilconazole, and miconazole.
 - Lime-sulfur: 8 ounces/gallon of water
 - Enilconazole (Imaverol™) available in the United States as Clinafarm EC™; see Drug Formulary, [Appendix 8](#); 0.2% emulsifiable concentrate, licensed for use as an environmental disinfectant, used off-label in the treatment of dermatophytosis at a dilution of 55.6 ml/gallon of water as a topical antifungal.
 - Miconazole available as shampoo formulation, either as a sole agent or combined with chlorhexidine.
- Twice weekly application as a whole body rinse or shampoo recommended.
- Topical therapy best used in conjunction with systemic antifungal drugs.
- If topical therapy used as a sole therapy, hair coat should be clipped and either lime-sulfur or enilconazole used.
- Do not use spot treatment.
- Do not allow cats to lick or groom off the antifungal solutions.

Modified and used with permission from Moriello KA. 2003. Dermatophytosis Symposium, Parts 1-4, Vet Med 98:844-891.

Table 58-7 Efficacy of Various Topical Agents Recommended for Treatment of Dermatophytosis in Dogs and Cats^a

TOPICAL AGENT	AVAILABLE FORMULATIONS	COMMENTS ON EFFICACY
Captan	Shampoo, rinse	Poor performance in vitro
Chlorhexidine	Shampoo, rinse	No advantage over control treatment in experimental clinical infection; inferior in in vitro tests ^b
Clotrimazole	Cream, lotion	Creams and lotions not formulated to penetrate infected hair
Enilconazole	Rinse, fogger	Superior in in vitro tests
Ketoconazole	Shampoo, cream	Tested in animal models, fair efficacy; creams not formulated to penetrate infected hair
Lime-sulfur	Rinse	Superior at 1:16 dilution in in vitro tests
Miconazole	Shampoo, cream	Superior in in vitro tests ^b
Povidone-iodine	Shampoo, rinse, ointment	Poor performance in vitro
Sodium hypochlorite	Rinse	Inferior (1:10 dilution) in in vitro tests

^a In vitro tests performed with infected hair.

^b Combined 2% miconazole/chlorhexidine shampoo has been more effective than either agent alone.

Miconazole is also an effective topical antifungal in both in vitro and in vivo studies.^{136,187} Important to note is that, in the in vivo studies, miconazole was used twice weekly as an adjunct to systemic therapy, rather than as sole therapy. As with all medicated shampoos, a skin contact time of 10 minutes is recommended for optimal therapeutic effect. This product can be irritating to the eyes and can cause skin irritation. Synergism

Infectious Diseases of the Dog and Cat, 3rd Edition

between miconazole and chlorhexidine has been demonstrated in vitro,¹⁸⁷ and shampoos with this combination of ingredients are documented to hasten mycologic cure.²¹⁶

† References: 97, 103, 136, 182, 187, 216.

58.1.6.3 Systemic Therapy

The role of systemic therapy in treating dermatophytosis is to accelerate resolution of the infection in the individual animal. Several effective drugs are available, and the appropriate choice must be made depending on cost considerations, fungal species, patient species, and potential toxicities. Development of standardized methods for antifungal susceptibility testing of dermatophytes^{104,109} permits testing of apparently resistant strains to determine which systemic drug may be optimal, but such testing is currently limited in availability.

560

561

These drugs should be used only when the diagnosis is certain. See [Chapter 57](#) and Drug Formulary, [Appendix 8](#), for further information on each of these drugs discussed here.

58.1.6.3.1 Griseofulvin

Griseofulvin (GFV) is declining in use because of its still relatively high cost, potential toxicities, and availability of other drugs. GFV is poorly water soluble; thus GI absorption after oral dosing is variable and incomplete. Absorption is enhanced by administration with a fat-containing meal. The original microsize-particle formulations are mostly no longer manufactured, being replaced by ultramicrosize formulations in polyethylene glycol, which are better absorbed. Even the latter formulations are increasingly difficult to obtain because popularity of the drug has declined. Dosages recommended for dogs and cats differ and are not based on modern pharmacologic studies. Dosages that have proved to be effective in the largest number of cases are higher than manufacturer recommendations, and significant toxicities may be encountered. The most common adverse effects are vomiting, diarrhea, and anorexia. These effects can be partially avoided by dividing the daily dose into two administrations. Bone marrow suppression and neurologic signs have occurred, unrelated to dose or treatment length, as idiosyncratic reactions. Myelosuppression has particularly been reported in cats with feline leukemia virus and feline immunodeficiency virus infection, and this drug should not be used if such infection is present. Leukopenias can be severe (even life threatening) and unpredictable; thus blood counts at monthly intervals are recommended when using GFV. The drug should not be used in animals younger than 6 weeks of age. GFV is teratogenic and must never be given during the first two thirds of pregnancy.

58.1.6.3.2 Imidazoles and Triazoles

Ketoconazole (KTZ) is a moderately effective fungistatic drug against *M. canis* and *T. mentagrophytes*. It has been used successfully to treat canine and feline¹⁴³ dermatophytosis. Less favorable results were reported in longhaired animals. Because of its potential toxicity, KTZ should be reserved for patients in which intolerance of GFV is a problem and in which itraconazole (ITZ) cannot be substituted because of greater expense. Side effects of KTZ include vomiting, hepatotoxicity, and inhibition of steroidal hormone synthesis.

ITZ is an oral triazole antifungal that is fungistatic at low tissue concentrations but fungicidal at higher concentrations. ITZ is better tolerated by cats and dogs compared with either KTZ or GFV and is comparable or superior to GFV in its efficacy against *M. canis*.^{126,132,165} In human medicine, ITZ has

Infectious Diseases of the Dog and Cat, 3rd Edition

proved helpful in chronic, recalcitrant dermatophytosis, including onychomycosis.^{64,98,100,208} Signs of hepatotoxicity have been reported rarely in cats, and idiosyncratic cutaneous vasculitis is reported in dogs. Nearly all patients, however, tolerate the drug well at the dosages recommended for treatment of dermatophytosis. ITZ is not recommended in pregnancy. The drug is available in 100-mg capsules that can be opened, divided, and dispensed to small animals in butter or food in the appropriate doses or as an oral liquid (10 mg/ml) that is useful for dosing very small animals or kittens (see Drug Formulary, [Appendix 8](#)). Many clinicians have used ITZ in kittens as young as 6 weeks.

ITZ, along with the other triazoles, persists in skin and nails for weeks to months after administration to people, and intermittent or *pulse* therapy is frequently prescribed for skin infections or onychomycosis.¹⁰⁶ Persistence of ITZ in the skin of dogs or cats has not been studied, but intermittent administration protocols appear effective. One study reported efficacy in cats with daily administration for 28 days, then every-other-week administration until cured.⁴⁶ The authors routinely use ITZ for feline dermatophytosis on a one-week-on, one-week-off schedule, with apparent efficacy at one half the total drug cost. ITZ solution (Itrafungol, 52 mg/ml) is licensed for use in cats in some countries but not in the United States; however, a similar preparation is licensed for use in people. ITZ has become a common, and perhaps even preferred, treatment for feline dermatophytosis because of its strong efficacy, ease of administration, and low incidence of toxicity. Because of its relatively high cost, this treatment is generally not practical for dermatophytosis in medium- to large-breed dogs.

Fluconazole (FCZ) is another triazole antifungal used primarily for treating human candidiasis. It has not been evaluated for its efficacy in treatment of dermatophytosis in dogs or cats. In an experimental guinea pig model, FCZ and ITZ administered at the same dosages were equally effective in clearing *T. mentagrophytes* infections.¹⁷⁶ However, in vitro studies, examining minimum inhibitory concentrations (MIC) of antifungal agents for various dermatophyte species, reported that mean MICs for FCZ were approximately 10 to 100 times higher than the MICs for ITZ, KTZ, or voriconazole.^{83,186} These data suggest that FCZ may be less useful for treatment of dermatophytosis than are other drugs of the same class, and limited clinical experience supports this contention. Thus no therapeutic or cost advantage can be found of FCZ over ITZ for dermatophyte infections. Triazole derivatives on the horizon include voriconazole and posaconazole; neither is primarily intended for dermatophytosis, and neither has been extensively evaluated in dogs or cats.

58.1.6.3.3

Terbinafine

This allylamine antifungal agent is indicated primarily for dermatophytosis but also has activity against other fungi such as *Aspergillus* and *Candida*.²⁰⁵ Terbinafine is fungicidal by virtue of its inhibition of the enzyme squalene epoxidase, which is necessary for fungal ergosterol biosynthesis. It is available in both topical (cream) and oral (tablet) formulations. Oral doses necessary to achieve fungicidal concentrations in hair of cats are higher by twofold to sixfold than human doses because of the differences in drug metabolism in cats.^{120,131} Various dosages ranging from 8 to 40 mg/kg/day have been used for treatment of feline *M. canis* infection.^{119,120,131} Doses at the higher end of this range (30 to 40 mg/kg) are demonstrably superior to lower doses, which may not produce resolution faster than spontaneous recovery.^{39,120} One cat with dermatophytic pseudomycetoma was treated with terbinafine at only 15 mg/kg/day without success.²⁵ Reported adverse effects include occasional vomiting^{131, 160} and elevation in serum ALT concentrations.⁴² The latter occurs in approximately one third of cats treated and is typically without clinical significance, but monitoring of liver enzymes is advised with use of terbinafine

Infectious Diseases of the Dog and Cat, 3rd Edition

in cats. The drug reaches especially high concentrations in sebum and the stratum corneum, and fungicidal concentrations may persist in the skin for several weeks after administration in people, suggesting that intermittent dosing regimens may be possible.¹³¹ Intermittent dosing has not been evaluated in human beings or cats to date. Terbinafine is not licensed for veterinary use, is very expensive, and its use in dogs has not been reported.

58.1.6.3.4

Lufenuron

Lufenuron (LFN), a benzoylphenylurea drug that disrupts chitin synthesis, is used worldwide for the control of fleas on cats and dogs. Chitin is a critical structural component of the exoskeleton of arthropods, such that interference with its synthesis prevents normal development of immature fleas and leads to disruption of the flea life cycle.⁵³ Chitin is also a component of the outer cell wall of fungi, including dermatophytes. Possibly, some compounds that disrupt chitin synthesis might also have antifungal activity. An early, uncontrolled trial of LFN in dogs with *Coccidioides immitis* infection

561

562

suggested possible clinical efficacy.⁴ However, in further controlled studies, LFN treatment resulted in neither in vitro inhibitory activity of *C. immitis* nor in extended survival of mice with experimental coccidioidomycosis.¹¹⁰ A case report described apparent success in treating equine fungal endometritis with LFN.¹⁰¹ In a retrospective epidemiologic study, LFN treatment was strongly associated with recovery of a large number of dogs and cats from a variety of superficial fungal infections, including dermatophytosis.⁶ This study led to widespread speculation about the potential usefulness of LFN as an antifungal treatment or preventative drug (or both) for dermatophytosis.

In a controlled experimental infection study,^{168a} LFN treatment of cats at 30 or 130 mg/kg orally (PO) did not prevent establishment of *M. canis* infection, when the challenge infection was induced by application of fungal spores to the skin. However, a slight delay was noted in establishment of the infection in the LFN-treated cats, as compared with control cats. In a subsequent study, clinically healthy cats treated with four doses of LFN at 100 to 133 mg/kg PO or 40 mg/kg subcutaneously (SC) at monthly intervals were exposed to a cat with mild *M. canis* infection.⁶² Treated cats received five monthly doses thereafter. All treated healthy cats became infected, although it again appeared that the onset of the infection was delayed slightly. Continued LFN treatment did not result in faster resolution of the infection than did the placebo treatment. A field study in two *M. canis*-infected catteries reported that addition of LFN to topical enilconazole treatment resulted in more rapid improvement of clinical signs in one cattery but not the other.⁹⁶ Thus inconsistent clinical results have been obtained with treating feline dermatophytosis with LFN, which may reflect fungal strain variation or variation in study methodology. Current evidence does not favor use of LFN for prevention or treatment of dermatophytosis, particularly with the availability of drugs with documented efficacy, such as ITZ.

58.1.6.4

Duration of Treatment and Followup Examinations

Cats or dogs with dermatophytosis should be treated until complete resolution of clinical signs (*clinical cure*), and then continued until the fungus cannot be cultured from the haircoat, on at least two sequential cultures a week or more apart (*mycologic cure*). The followup cultures can begin as early as 3 to 4 weeks after treatment is instituted and thereafter on a 2-week schedule. Once the culture results are negative, monitoring can be on a once-weekly basis. At least two negative culture results in single-cat households and three in multiple-cat environments are recommended. Cats can appear clinically healthy before their skin and hair are cleared of fungal organisms. Although a Wood's light can help screen for dermatophytes, it is not a

Infectious Diseases of the Dog and Cat, 3rd Edition

good tool to monitor the progress of infection in an individual cat because positive fluorescence may occur in some hair shafts in which fungus has been inactivated.¹⁵⁸

58.1.6.5

Treatment Failure

With competent immune systems, cats with dermatophytosis usually resolve their clinical illness within 100 days.⁴ Clinical improvement usually begins to occur within 2 to 4 weeks of starting treatment. Early improvement is characterized by a reduction in pruritus, erythema, scaling, and hyperpigmentation. If the animal's hair has been clipped, hair growth will begin but may not be complete for several months. Incorrect diagnosis and lack of elimination of infection or reinfection are reasons that therapy can be unsuccessful. Given that dermatophytosis mimics many other skin diseases, an incorrect diagnosis is a major reason that clinical signs may not resolve following use of antifungal therapy. Relapses usually result from inadequate duration or type of therapy. Failures are caused by owner compliance, incorrect dosing, or antifungal resistance. The muzzle should be checked carefully, given that it can remain affected because of the hesitancy to put topical medications near the face or from reexposure through facial contact with the environment or carrier animals. Immunosuppression can be caused by concurrent infections, systemic illnesses, or medications. These conditions include endocrine diseases such as hyperadrenocorticism, hyperthyroidism or hypothyroidism, cytotoxic or glucocorticoid therapy, demodicosis, and retroviral infections. Reinfection is caused by inadequate decontamination of the environment or elimination of infection in inapparent carrier animals. Clipping of the haircoat may be imperative in some animals.

58.1.6.6

Environmental Control

M. canis spores can persist in the environment for long periods; spores have remained viable in the authors' laboratory for several years. The spores are microscopic and can easily be spread via air currents, contaminated dust, heating vents, and so forth. Contaminated environments are underrecognized in their importance as reservoirs of infection for people and other cats. In addition to general cleanliness, the amount of environmental contamination is directly related to the number of animals involved in the outbreak and the duration the animals have spent in the home before the infection is recognized.⁴ General environmental control recommendations are summarized in [Table 58-8](#).

Label claims of fungicidal activity for disinfectant products are determined by testing the compound against the mycelial form of a dermatophyte or macroconidia and not against the form actually found in contaminated premises (i.e., infected hair fragments, arthrospores). A disinfectant inactivates virtually all recognized pathogenic microorganisms on inanimate objects but not necessarily all physical forms (spore forms) of the microorganism. In the case of dermatophytosis, a product may be appropriately labeled as fungicidal (because it kills mycelial forms) yet be ineffective against arthrospores (i.e., the naturally infective state in the environment). Studies have shown that many previously recommended disinfectants and products commonly used in veterinary clinics are ineffective as agents for dermatophytosis.^{166,169} The only solutions shown to be 100% fungicidal after a single application were agents such as 1% formalin and undiluted household chlorine bleach. Neither of these solutions can be used in the home because of the human health safety concerns and because both are too caustic. The antifungal activity of many products is limited in the presence of organic material. In addition, fungal elements within hair shafts may be protected from disinfectants. Also important to note is that these products may not be effective on contact; a minimal wetting time for the surface of 10 minutes is recommended.

Infectious Diseases of the Dog and Cat, 3rd Edition

Studies using isolated infected hairs or spores or field studies using dermatophyte-contaminated environments have shown that the following disinfectant products are consistently effective: lime-sulfur (1:33), enilconazole (0.2%), and 1:10 to 1:100 household chlorine bleach.^{97,159,169,230} In addition, a study has also shown that strain variation of *M. canis* with respect to susceptibility to disinfectants is not present.¹⁶⁹ In this study, all 10 strains were susceptible to lime-sulfur, enilconazole, and 1:10 bleach. None of the strains were susceptible to any dilution of, including four times the recommended concentration of, chlorhexidine or detergent-peroxide disinfectant. Rather than variations in strain susceptibility to disinfectants, *resistant* infections are likely caused by inadequate decontamination procedures.

For treatment of routine infections with one or a few animals in the household, extensive environmental decontamination is generally impractical and unnecessary. Thorough vacuuming and mechanical cleaning will remove much infective material. All hard surfaces should be mopped with disinfectant such as a 1:100 bleach solution. During treatment, these few animals should be confined to a small easily cleaned room without carpeting until they have received systemic antifungal therapy for at least 2 weeks and have been dipped at least four times with topical preparations such as lime-sulfur. Cat beds and blankets can be washed daily in hot water and bleach.

562

563

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 58-8 Recommendations for Mechanical Cleaning and Disinfection of Surfaces^a

To Start

- Remove and discard or disinfect all cat rugs, blankets, collars, brushes, fabric toys, etc.
- Discard any other object that cannot be repeatedly vacuumed, scrubbed, and disinfected.
- Purchase a new vacuum cleaner with hose attachments in price range that will allow it to be ultimately discarded.
- Remove all drapes, decorative objects, and so forth from the room and clean them.
- Remove all heating duct covers and vents for washing. Install piece of disposable furnace filter behind the metal duct plates before replacing them. These can be purchased at almost all home improvement stores and will help keep spores from being spread through heating ducts.
- Commercial cleaning of heating and cooling ducts may be needed in some catteries.
- If possible, put a fan in the window and set it so it draws air out of the room to the external environment.
- Thoroughly vacuum ALL surfaces of the room.
- Dust all surfaces, ledges, and so forth with disposable dusting cloth.
- Scrub all surfaces with a detergent that is safe to use around pets. Rinse all surfaces well; ideally, use a wet-dry vacuum to remove the dirty water.
- Apply a 1:10 to 1:100 dilution of household bleach to all nonporous surfaces, or use enilconazole emulsifiable concentrate (Clinafarm EC™ [Janssen Pharmaceuticals, Titusville, N.J.]; distributed by American Scientific Laboratories, Union, N.J.) or smoke generator. Note: read labels for contact and wetting time. Surfaces treated with bleach need to be wetted for at least 10 minutes for maximal fungicidal action. USE APPROPRIATE VENTILATION AND PERSONAL PROTECTIVE EQUIPMENT (gloves, eye protection).
- Use a portable dehumidifier in cat rooms to keep humidity low; humid environments favor spore viability.

Daily

- Vacuum all surfaces and use disposable dust cloths to remove dirt and spores.
- Depending on the number of cats in the room, wash floors and any surfaces contacted by cats with detergent. Use of mops with disposable detergent pads is recommended.

Weekly

- Thoroughly vacuum, dust, and scrub all surfaces in contact with cats.
- Apply disinfectant to all surfaces. Allow adequate contact time. Rinse thoroughly.

Preventing Spread in Catteries

- Use plastic sheeting on the inside of the doorway to prevent spores from escaping.
- Use disposable trash bags to cover clothes while treating cats or cleaning rooms.
- Change shoes before and after leaving cat treatment area.

Infectious Diseases of the Dog and Cat, 3rd Edition

- Do not run air conditioners in room if this action blows air throughout the house.

a Modified and used with permission from Moriello KA. 2003. Dermatophytosis Symposium, Parts 1-4, Vet Med 98:844-891.

In the instance that an infected cat has been introduced into a previously unaffected household, the extent of infection in other cats and the environment can often be limited with early intervention. Where the new animal has not been confined, infection is first noted in the most social cats and often is found on their head and ears. The degree of environmental contamination is usually low. However, if culture results reveal infection in the least social cats, the environment must be considered as contaminated, and disinfection procedures are warranted.

In an animal shelter or cattery with endemic infection, extensive environmental disinfection is critical. A thorough vacuuming of the environment is the first step; no visible hairs should be present. This step is followed by thorough cleaning with a routine household detergent; suction of the wet solution from surfaces is recommended and can be accomplished using inexpensive wet-dry vacuum cleaners. After cleaning, liberally apply 1:10 to 1:100 (i.e., 1 ounce/gallon) bleach, or appropriately diluted enilconazole. The latter is available in the United States as an emulsifiable concentrate or smoke generator. See Drug Formulary, [Appendix 8](#), for further information. In the United States, enilconazole products are registered with the Environmental Protection Agency for use in poultry houses to control aspergillosis in the environment but are not registered for other uses. Enilconazole is safe for human exposure when guidelines are followed, but it can be corrosive. Chlorhexidine is not an effective disinfectant for dermatophytes. In an animal shelter or similar facility, environmental disinfectants may be conveniently applied (with suitable skin and respiratory protection used by personnel) using a pressurized garden-type sprayer.

58.1.6.7

Special Considerations for Infected Multiple-Animal Facilities

Endemic dermatophytosis has a profound effect on the health, community reputation, and economic status of animal breeding colonies and animal shelters. Breeding programs must be interrupted because newborn animals are rapidly and easily infected, leading to debilitation and sometimes death. Adoption of shelter pets must be temporarily halted to avoid spread of the infection to new owners. Eradication of dermatophytosis from such a facility is completely possible but very expensive and time consuming; thus every attempt must be made to do the job correctly the first time and to institute preventive measures against future outbreaks.

Important to recognize is that animals with visible, obvious lesions represent only *the tip of the iceberg* in an endemic colony, particularly in a *M. canis*-infected cattery. Many animals will also have subclinical infections, and many more will be innocently carrying dermatophyte spores on their haircoats. Therefore the eradication process must begin by toothbrush culturing (see previous discussion, Specimen Collection) every animal in the facility, regardless of clinical appearance. Beginning an eradication effort with 50% to 100% of animals with culture-positive results is not unusual, though not all of these may be actually infected. While awaiting the initial culture results, quarantine any animals with obvious or suspected infection. This precaution requires isolation in a separate *contaminated* room or building, with floor surfaces that can be disinfected easily. A Wood's lamp is very helpful here, if the outbreak is caused by a fluorescing strain. A separate *clean* room or building must also be prepared into which cured animals will be gradually moved. If new animals must be introduced into the colony during the eradication effort, as is common for an animal shelter, a separate, third *intake* room or building must be prepared, where new arrivals will be quarantined until it is certain they are not infected. Environmental decontamination procedures should begin immediately in all three rooms, as previously detailed, and repeated monthly for the duration of the entire decontamination effort.

563

564

Infectious Diseases of the Dog and Cat, 3rd Edition

Once the initial results are known, the animals can be divided into two groups based on culture result and clinical appearance. The first group consists of lesion-free animals with negative culture results, and is typically fairly small. These animals should be bathed with a miconazole-chlorhexidine or KTZ-chlorhexidine shampoo, followed by a dip in lime-sulfur or enilconazole. They can be immediately transferred to the *clean* room. Animals that have visible lesions or have positive culture results, or both (even if normal in appearance), are assigned to the *contaminated* room, and this will initially be the majority of animals.

All animals in the *contaminated* room are treated. If feasible, clipping the hair short on all longhaired animals is desirable. If clipping is not practical, at the very least, any visible lesional areas should be clipped. This step will eliminate a great deal of infective material that otherwise would be spread into the environment. All animals are bathed with an antifungal shampoo and dipped in lime-sulfur, and the bath and dip are repeated twice weekly for the duration of the effort. Concurrently, begin oral antifungal treatment on all animals, with daily GFV or alternate-week ITZ as previously detailed. See [Table 58-5](#).

A key to successful eradication is careful monitoring by culture. Followup toothbrush fungal cultures are obtained from animals at intervals of approximately 2 weeks. Animals in the *clean* room should be recultured once after being transferred to that room, as a precautionary measure. Animals in the *contaminated* room are cultured every 2 weeks until each animal has a negative result on at least two successive times. Animals that initially had positive culture results but only carrying a few spores (as opposed to being actively infected) will develop negative results rapidly, and as they achieve two cultures with negative results, they can be transferred to the *clean* room. It will soon become obvious which animals are truly infected because these individuals will have multiple successive positive culture results even during treatment. Treatment is continued in the *contaminated* room until all animals are cured and moved to the *clean* room. At this point, the *contaminated* room should be thoroughly cleaned and decontaminated before further use.

During treatment, watch for animals that have persistently positive culture results, with many colonies on the culture plate and little apparent resolution despite treatment. These animals, which will typically be only one or a few, may be chronically infected by virtue of their failure to develop appropriate CMI, and they represent a potent threat to the continued health of the entire colony. Recommendations are that these chronically infected animals be removed entirely to a separate facility for treatment or euthanized.

Each animal in the *contaminated* room may require from 4 to 12 weeks of treatment before having two consecutive negative culture results. In a typical animal shelter with 50 to 100 cats, the entire eradication process will last 5 to 6 months. If, for some reason, separate *clean* and *contaminated* areas cannot be prepared, the authors have had occasional success in eradication by simply treating all animals in the entire facility as *contaminated* and continuing treatment until all animals have two consecutive negative culture results.

If new animals are entering via the *intake* room, as each animal enters, it should be immediately toothbrush cultured, followed by an antifungal bath and dip. Most animals will have negative culture results and can be transferred to the *clean* room as the culture results become known. Any animal that has a positive culture result is transferred to the *contaminated* room and treated as previously noted. After the eradication effort is concluded, this *intake* procedure should be maintained indefinitely. In the authors' experience, for 1 out of every 15 to 20 new animals entering a shelter to have positive culture results is not unusual, and this animal would be capable of starting a new endemic infection in the whole facility if not discovered. In a show cattery, this principle applies also to any cat coming back into the facility from a cat show or breeding loan.

Infectious Diseases of the Dog and Cat, 3rd Edition

58.1.7 Prevention

In an indoor-cat household, the most likely risk of infection is introduction of an infected cat or exposure of an existing cat that has been to a veterinary hospital or boarding or grooming facility where the infection exists. All new dogs or cats entering a dermatophyte-free environment should be screened for infection by culture and simultaneously treated with lime-sulfur if it originates from a multiple-cat environment. Cats that come into contact with spores from the outside on short absence should generally be able to eliminate the spores through grooming; however, at least, a preventative dip in lime-sulfur is warranted. Longhaired cats that become exposed for several days or more constitute the greatest risk and should be quarantined and cultured until the results are known. For catteries without dermatophytosis, periodic screening of the environment and animals by culture will detect reintroduction or relapses before they spread. Strict cleaning and disinfection in the environment, as previously outlined, are beneficial in preventing introduction and spread. Cats at shows should be placed in carriers with cloth coverings to help protect against spore contamination. Visitors to the cattery should wear protective clothing and should not have contact with cats if they have had been handling infected cats.

Knowledge of the immunology of dermatophytosis has led to some dramatically effective programs of vaccination and eradication of ringworm from food and fur-bearing animals in many countries, and reasonable hope exists that the same observations extended to companion animals will someday result in the possibility of prophylactic vaccination in these species.

564

58.1.7.1 Vaccine Development

565

Early investigations demonstrated that inoculation of various preparations of living or killed dermatophytes by SC, intramuscular, intraperitoneal, or even topical routes produced both positive intradermal test results and partial resistance to further infection. The resistance was often incomplete and of short duration. In species such as cattle and fur-bearing animals, further investigation of the immunologic response of the host to dermatophytic fungi led to the development of highly effective vaccines. Historically, the greatest successes came with injection of live mycelium or viable spores. The biologics industries in Eastern Europe were active early in development of vaccines for use in cattle, horses, and foxes. Vaccines that were developed included LTF-130 for cattle, SP1 for horses, and TM-135 for foxes and rabbits. Vaccination programs have essentially eradicated bovine dermatophytosis from several European countries, with a concomitant decrease in human infections. All of these vaccines were intended to prevent animals from developing *Trichophyton* infections.

Two experimental vaccine preparations have been studied in cats. A killed *M. canis*– cell wall vaccine induced both antibody titers and CMI in laboratory cats, but these responses were not as strong as those seen in natural infection and did not confer resistance to challenge infection.^{56,58,62} Combined live-inactivated dermatophyte vaccine, consisting of attenuated live *Trichophyton* with killed *Microsporum* components, was tested in cats under laboratory conditions. Again, the vaccine induced a specific immune response; the response was not protective against direct challenge infection but produced a trend for reduced severity of initial infection.⁶¹ The most recent vaccination efforts involve injection with recombinant proteases of *M. canis* origin, but initial studies in guinea pigs have been disappointing.⁷⁰ A commercial product (Fel-O-Vax MC-K) consisting of killed dermatophyte components in adjuvant had been marketed in the United States for feline use but is no longer available. The major indication for this commercial vaccine was for reduction in severity of the clinical signs of dermatophytosis in cats; it was not protective against infection induced by

Infectious Diseases of the Dog and Cat, 3rd Edition

direct topical application of spores.⁶¹ Apparently, the goal of a truly prophylactic vaccine against feline dermatophytosis has not been attained, but success in other species and increasing knowledge regarding the immune response of cats and experimental infections hold promise that this goal will be eventually achieved.

58.1.8 Public Health Considerations

58.1.8.1 Pet Owners and Animal Health Workers

Dermatophytosis is a zoonotic disease and is of particular concern in certain at-risk populations. These groups include children, transplant and cancer patients, people with debilitating or immunocompromising diseases, and older adults. Immunocompromised persons may be at increased risk for infections and for more serious infections.¹¹⁷ In addition, everyone in the health care professions must take precautions to avoid contracting the disease because it can limit their ability to work with patients. One of the authors is aware of a physician who contracted *M. canis* from a kitten and was not able to return to work for 4 months. Any animal acquired from an animal shelter, rescue agency, or breeding facility poses an increased risk of being infected or mechanically carrying spores on its haircoat. These animals should have fungal cultures performed on toothbrush-collected specimens as part of their routine examination and testing. Cats used in facilitated therapy for human rehabilitation should be tested on a biannual basis. Approximately 50% of people exposed to either symptomatically or asymptotically infected cats develop lesions (Fig. 58-7), and in 70% of all households with an infected cat, at least one person usually contracts the disease.¹⁸⁵

Worldwide, the reported number of cases of human infection with *M. canis* continues to increase.²⁰¹ The author's opinion holds that a fungal culture should be part of all new animal examination and testing procedures.

Fig 58-7 Ringworm lesion on the forearm of a cat owner. (Courtesy University of Georgia, Athens, Ga.)

For handlers of small animals, the occupational risk of acquiring dermatophytosis is not as great as it is for those working with cattle, for whom ringworm is the most commonly reported zoonosis. Not surprisingly, *M.*

Infectious Diseases of the Dog and Cat, 3rd Edition

canis is most often implicated in cases involving small animal practitioners and their employees. An investigation of veterinary clinics in Italy revealed that, in 15 of 50 clinics, *M. canis* could be isolated from the floors of waiting rooms, examination rooms, radiology rooms, and wards.¹³⁰ Veterinary practitioners must be vigilant in protecting themselves and their employees from this zoonosis.¹¹⁸

58.1.8.2 Interspecies Transmission

In one study on the fungal flora of cats, 14 isolates of *T. rubrum* were noted; this organism is an important human pathogen associated with tinea pedis (athlete's foot).^{79,162} After the report of this finding one of the authors (KAM) became aware of a household in which at least one cat was diagnosed with clinical dermatophytosis caused by *T. rubrum*. When informed of the diagnosis, the owner admitted to having chronic athlete's foot fungus and that he commonly rubbed his bare feet against the cat's haircoat.²⁰⁹ *M. canis* may be transmitted from people to household pets as well. *M. canis*-infected cats have been implicated as the source of infection in farm animals, including pigs, lambs, and rabbits.^{85,105}

58.2 MALASSEZIA DERMATITIS

Ross Bond

58.2.1 Etiology

Malassezia spp. (previously *Pityrosporum* spp.) are lipophilic yeasts that reproduce asexually by monopolar or sympodial budding. They are most often isolated from the skin and mucosal sites of clinically healthy mammals and birds. The genus is divided into two groups based on their lipid dependency in culture media. *Malassezia pachydermatis* is unique within the genus in that it can be cultivated on routine mycologic media without lipid supplementation. *M. pachydermatis* has been found to be genetically heterogeneous and to be in the process of differentiation, probably linked to animal hosts. Following a taxonomic revision of the genus, six lipid-dependent *Malassezia* species are recognized, namely *M. furfur*, *M. sympodialis*, *M. globosa*, *M. obtusa*, *M. restricta*, and *M. slooffiae*; these species require lipid supplementation for growth in vitro. Dogs are very frequently colonized by *M. pachydermatis* but very rarely colonized by lipid-dependent *Malassezia* spp.⁵⁰ Further information regarding the species within the genus and their identification by molecular methods has been published.^{90,93} Clinically healthy cats and cheetahs (*Acinonyx jubatus*) are often colonized by *M. pachydermatis* and occasionally by lipid-dependent species, including *M. sympodialis*, *M. globosa*, and *M. furfur*.^{16,49,51,102} A variant of *M. sympodialis* has also been isolated from a cat with otitis externa.¹⁰² Lipid-dependent species are frequently isolated from human skin where they are associated with a number of diseases,¹¹⁵ but *M. pachydermatis* is rarely isolated from human skin.

In dogs, *M. pachydermatis* is frequently isolated from the haired skin of the chin and lips, interdigital skin, and external ear canal and less often from other intertriginous areas such as the axilla and groin. Population sizes in healthy dogs are generally low but are markedly increased, often up to 10,000-fold, in many cases of *Malassezia* dermatitis, although overlap in population densities can be found between some healthy and affected dogs. The anatomic sites most often colonized in healthy animals correlate with regions most often affected in dogs with skin disease caused by the yeast. For a discussion of *M. pachydermatis* in otitis externa, see [Chapter 85](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Malassezia dermatitis is commonly seen in dogs but is much less frequent in cats. A change in host immunity, altered skin microclimate, or disruption in epidermal physiology may predispose animals to develop clinical disease, although the factors that favor the transition from commensalism to parasitism are poorly understood. Further studies are required to elucidate the innate and adaptive events involved in the immunoregulation of the yeast and its interaction with the cells of the epidermis in both health and disease. *Malassezia* dermatitis may be the only disease recognized in some dogs, but in others, concurrent disorders such as allergies, especially atopic disease, keratinization defects, endocrinopathies, and the presence of skin folds may be important in favoring the yeast. Breed predilections vary between geographic regions but may include basset hounds, West Highland white terriers, cocker spaniels, toy and miniature poodles, dachshunds, boxers, Cavalier King Charles spaniels, shih tzus, Australian and silky terriers, and German shepherd dogs. Affected cats may also have underlying allergic and metabolic diseases, but immunosuppressive viruses such as feline leukemia virus and feline immunodeficiency virus, and paraneoplastic disorders (pancreatic paraneoplastic alopecia, exfoliative dermatitis with thymoma), may also favor infection. Bull terriers with lethal acrodermatitis are known to have impaired immune function, and they harbor large numbers of *Malassezia* on their skin.¹⁴¹ *Candida albicans* co-infection may be partly responsible for lesions in the nails and footpads of these dogs.

Both healthy and affected dogs develop serum IgG antibodies that recognize *Malassezia*-derived proteins; titers are increased in dogs with disease.^{14,178} Western immunoblotting showed that more protein bands are detected by sera from diseased dogs.^{21,44} Some dogs with atopic disease show immediate reactivity to intradermal injections of *Malassezia* antigens, suggesting that hypersensitivity to yeast antigens may exacerbate the clinical signs of atopic disease in some individuals.^{13,172} Elevated serum IgE titers to *M. pachydermatis* have also been demonstrated in dogs with atopic disease,¹⁷⁸ frequently associated with immunoreactivity to allergens of 45, 52, 56 and 65 kDa.⁴⁵ By contrast, basset hounds with *Malassezia* dermatitis usually show delayed rather than immediate skin test reactivity to *Malassezia* antigens, indicating that a spectrum of immunologic responsiveness is present in dogs with *Malassezia* dermatitis.²⁴

58.2.2 Clinical Findings

58.2.2.1 Dogs

Clinical signs may be localized or generalized. In dogs, the disease is most often seen at anatomic sites that create a relatively warm, moist skin environment. Thus the interdigital skin, ventral neck, lip region, ear canal, axilla, groin, and folded areas are most often affected. Pruritus is normally reported and ranges in degree from mild to severe. Erythema accompanied by greasy exudation is commonly observed, especially in intertriginous areas where a brown exudate may mat the lower portion of the hair; malodor may be noted with extensive exudative lesions (Figs. 58-8 and 58-9). Traumatic alopecia, lichenification, and hyperpigmentation may develop in dogs with marked pruritus (Fig. 58-10). Paronychia (nail fold inflammation) associated with *M. pachydermatis* may lead to pedal pruritus accompanied by reddish-brown discoloration of the claw and or exudation in the nail fold. The isolation rate of *M. pachydermatis* from the eyes of dogs with corneal ulcers was greater than that from clinically healthy dogs,^{196a} suggesting some role for its presence in the development of these lesions.

A seasonal increase in case numbers may be observed in geographic regions where a noticeable change to warm, humid climatic conditions is present. Typically, the response to glucocorticoid therapy is poor.

Infectious Diseases of the Dog and Cat, 3rd Edition

58.2.2.2 Cats

M. pachydermatis appears to be a relatively infrequent pathogen in cats, at least when compared with dogs. This finding may reflect the lower carriage rates of the yeast in healthy cats^{15,16,52}. The isolation rate from the ear canal is lower in clinically healthy cats compared with those with otitis.^{176b} Ceruminous otitis externa responsive to antifungal eardrops is the most common clinical presentation of *M. pachydermatis*-associated skin disease in cats but occasional cases of localized or generalized *M. pachydermatis*-associated dermatitis have been described. Exfoliative erythroderma, greasy exudation, and varying degrees of pruritus may be seen. Cats with exfoliative dermatitis associated with thymoma⁸⁰ and paraneoplastic alopecia may have concurrent proliferations of *Malassezia*.⁸⁴

The pathogenicity of lipid-dependent *Malassezia* spp. in cats has not yet been fully determined^{51,52}; *M. sympodialis* has been isolated from the external ear canals of cats with otitis externa. The author is aware of sporadic unpublished cases in which *M. sympodialis* has been implicated in more generalized dermatitis in cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

58.2.3 Diagnosis

The clinical signs of *Malassezia* dermatitis are not pathognomic, and the disease should be routinely suspected in dogs with inflammatory skin diseases, especially those with erythema or greasy exudation as a dominant presenting sign. *Malassezia* dermatitis may mimic or complicate atopic disease and dietary sensitivity. Seborrheic presentations and fold-associated diseases should also prompt an evaluation of the presence and numbers of the yeast.

The diagnosis is based on clinical signs, presence of elevated numbers of the yeast in lesional skin, and a clinical and mycologic response to antifungal therapy. In clinical practice, yeast numbers are most usefully assessed by cytologic examination. Impression smears can be made directly onto glass slides, or exudate can be transferred to the slide using swabs. However, the author prefers the tape-strip method; clear cellophane tape is pressed on the surface of the skin, thus collecting the stratum corneum cells and any superficial microbes. Unlike direct impressions, tape stripping can be used effectively in most anatomic sites and in dry or greasy lesions. The tape is stained, usually with a modified Wright stain, and examined using the light microscope (Fig. 58-11). Normally, the characteristic peanut-shaped *Malassezia* spp. yeast cells are rarely seen in healthy skin but are usually readily identified in specimens from affected individuals.

Fig 58-11 Tape-strip preparations stained with Diff-Quik and examined using the ×100 objective are useful in the assessment of *Malassezia* populations on skin. Numerous *Malassezia* yeast cells with their characteristic morphology associated with monopolar budding can be seen amongst stratum corneum cells, indicating an elevated population. (Courtesy Ross Bond, Royal Veterinary College, Herts, United Kingdom.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Although some authors have proposed guidelines on the number of yeasts needed for significance (e.g., one or more yeast per high powered field), this approach does not accommodate the overlap seen in yeast population densities in skin samples from healthy and diseased dogs. In addition, quantitative cultural investigations have demonstrated important breed and anatomic site differences in population sizes in healthy dogs. Also possible is that hypersensitivity responses to yeast-derived allergens might enable a relatively small number of organisms to generate skin disease in sensitized individuals. Thus trial therapy is an important component in the diagnostic evaluation of *Malassezia* dermatitis. Therapy should be given whenever the yeast is readily identified in cytologic specimens obtained from consistent lesions.

Quantitative cultural techniques involving contact plates and detergent scrubs are primarily used in research rather than routine clinical practice, although the contact plate method is a useful method of isolating the yeast from the skin. Cellophane tape strip sampling described for cytology above can also be used to transfer cells to the surface of culture plates,¹⁸⁰ although the potential for an antimicrobial effect of the adhesive tape should be considered. *M. pachydermatis* can be isolated using Sabouraud's dextrose agar, modified Dixon's agar, or Leeming's medium, with optimal growth at temperatures between 32° C and 37° C (89.6° F and 98.6° F).⁹² Lipid-dependent species may be recovered using modified Dixon's agar or Leeming's medium; use of these media is preferred when samples are taken from cats in case lipid-dependent species are present. Skin biopsy specimens typically show marked irregular epidermal hyperplasia, spongiosis, and a superficial perivascular or interstitial infiltrate of mononuclear cells, with focal accumulations of neutrophils, eosinophils, and mast cells. Yeast cells may be seen in the stratum corneum, but the disruption of this layer that occurs during routine tissue processing may lead to an absence of the yeast; biopsy has a low sensitivity for yeast detection when compared with cytology (Fig. 58-12).

567

568

58.2.4 Therapy

Therapy is based around topical and or systemic antifungal therapy (Table 58-9).

58.2.4.1 Topical Therapy

The yeast is located in the stratum corneum, and thus topical therapy alone can be successful when potent antifungal agents are correctly applied. This approach depends on good compliance and availability of effective products. Topical therapy avoids the expense and potential toxicity of systemic azole drugs but is more labor intensive for the owner. A 2% miconazole–2% chlorhexidine shampoo has been available in a significant number of countries for several years and has been shown to be highly effective when used every 3 days for 3 weeks as the sole treatment. Other topical agents include azole-containing rinses, lotions and creams, and selenium sulphide and benzoyl peroxide-containing shampoos.

Fig 58-12 Skin biopsy specimen from a dog with *Malassezia* dermatitis. Large numbers of peanut-shaped *Malassezia* yeasts are present in the stratum corneum (methenamine silver, ×1000). (Courtesy Ross Bond, Royal Veterinary College, Herts, United Kingdom.)

Table 58-9 Drugs for Systemic Therapy of *Malassezia* Infection in Dogs and Cats

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION ^c (WEEKS)
Ketoconazole ^d	D	5–10	PO	12–24	2–4
Itraconazole ^e	D	5–10	PO	24	2–4
	C: daily therapy	10	PO	24	2–4
	B: pulse treatment	10	PO	24	First 2 days of each week
Terbinafine ^f	D	30	PO	24	3–4

a See Drug Formulary, [Appendix 8](#), for additional information on each drug.

b Dose per administration at specified interval.

c Followup brush culture results should be negative before discontinuing therapy.

d Trade name: Nizoral; generic available; cats often receive 50 mg total dose daily; with side effects, every other day treatment is used.

Infectious Diseases of the Dog and Cat, 3rd Edition

e Trade name: Sporanox; capsules may be opened and contents divided to administer recommended doses, or use oral solution.

f Effective in reducing *Malassezia* concentration in basset hound skin.^{90a}

58.2.4.2 Systemic Therapy

Both KTZ and ITZ are effective when given orally. KTZ may be used at doses ranging from 5 to 10 mg/kg, either once or twice daily, for 14 to 28 days. The antiinflammatory effects of this drug may also be beneficial. ITZ can be given at 5 to 10 mg/kg, PO, once daily for 2 to 4 weeks, and is less toxic and has better tissue penetration compared with KTZ. A pulse-therapy regimen of ITZ, 5 mg/kg daily, PO, for 2 successive days each week, has been described as an alternative to daily dosing.⁵ For additional information on these drugs, see Drug Formulary, [Appendix 8](#). GFV, the medication used to treat dermatophyte infections, is not effective in *Malassezia* infections.

58.2.5 Prevention

Failure to identify and correct concurrent diseases may result in relapsing infection. Intermittent or continuous maintenance therapy is often necessary in animals that experience relapsing disease, particularly in dogs with poorly controlled allergic disease or in dogs in which the reason for disease susceptibility cannot be identified.

58.2.6 Public Health Considerations

M. pachydermatis, for which dogs are natural reservoirs, is rarely associated with diseases in people. Owners of dogs with inflamed skin had a high rate of carriage of the organism.^{173a} A potentially fatal fungemia has been reported in premature babies and less often in immunocompromised adults.³ Most of the affected neonates were premature, had concurrent serious underlying disease, had central or peripheral catheters placed, and in some cases were receiving lipid emulsions as a component of parenteral nutrition. In one outbreak, *M. pachydermatis* was thought to have been transmitted from neonate to neonate on the hands of health care workers; the original source of the yeast was not identified, but transfer from pet dogs was suspected.⁴⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

59 CHAPTER 59 Blastomycosis

Alfred M. Legendre

59.1 ETIOLOGY

Blastomycosis is a systemic mycotic infection caused by the dimorphic fungus *Blastomyces dermatitidis*. In nature, *Blastomyces* grows in a saprophytic mycelial form (*Ajellomyces dermatitidis*) that reproduces sexually, producing infective spores (aleurioconidia). At body temperature in tissues the organism transforms into the yeast form and replicates asexually. The gene *bys-1* controls the change of the fungus from a mycelial to a yeast phase.²¹ Budding yeasts are 5 to 20 µm in diameter and have a thick, refractile, double-contoured cell wall. Dogs and people are the most commonly infected with *Blastomyces*, but cats, horses,⁷⁸ sea lions,⁸⁶ wolves, ferrets, and polar bears as well as lions and other captive nondomestic felines such as tigers, cheetahs, and snow leopards⁷⁷ have developed systemic blastomycosis.^{49,52} Blastomycosis was recently identified in a rhesus monkey.⁸⁰

59.2 EPIDEMIOLOGY

59.2.1 Natural Reservoir

The reservoir for *Blastomyces* is thought to be the soil; however, recovery of the organism from sites of suspected exposure is uncommon. Growth of the organism in the environment appears to require sandy, acid soil and proximity to water. Decaying wood by-products and animal waste substrates support growth of organisms.¹¹ Environmental survival of *Blastomyces* is also restricted because normal soil organisms in most areas destroy *Blastomyces* inoculated into the soil. A special set of environmental conditions—an *ecologic niche*—is required for proliferation of the organism. Organisms were recovered from a beaver dam where numerous schoolchildren were exposed to the organism.⁴⁶ Living near a waterway is a risk factor for blastomycosis infection. In Wisconsin studies, 95% of dogs with blastomycosis lived within 400 m of a body of water at altitudes less than 500 m above sea level.^{14,14a} The importance of proximity to water also was recognized in a Louisiana study in which dogs with blastomycosis were 10 times more likely to live within 400 m of water than control dogs.² Although proximity to water is a risk factor, exposure to the outside environment is not necessary because blastomycosis develops in strictly indoor dogs and cats.^{2,13,64} Rain or heavy dew appears to facilitate the release of infectious spores. Access to sites that have been excavated also increases the risk for infection because of exposure to organisms deep in the soil.¹⁴ In people, involvement in dirt-moving activities significantly increased the risk of developing blastomycosis.⁶⁴ Even within endemic regions, *Blastomyces* species are not widely distributed. Most people and dogs living in such areas show no serologic or skin test evidence of exposure. A point source of exposure within an enzootic area is more likely. For example, it is not unusual to find neighborhoods in which numerous dogs with blastomycosis are identified in a short time. In 14% of households in which blastomycosis has been diagnosed in the people or dogs, another case is diagnosed in the same household in the next several years.¹³ Dogs and people being exposed to a common source of infection while duck and raccoon hunting has been reported.^{4,72}

In other systemic fungal infections such as histoplasmosis (see [Chapter 60](#)), coccidioidomycosis (see [Chapter 62](#)), and aspergillosis (see [Chapter 64](#)), many animals are exposed, but few develop significant disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

However, in canine blastomycosis, subclinical infection is uncommon. When tissues from pound dogs in endemic areas were cultured for fungal organisms, *Blastomyces* organisms were found in 2%, and *Histoplasma* organisms were found in 50% of the dogs.⁷⁹

Two of 48 healthy dogs from an enzootic area for blastomycosis had antibodies to *Blastomyces* according to a radioimmunoassay (RIA), but an agar-gel immunodiffusion assay (AGID) for both dogs was negative.⁴⁵ The dogs had no history of respiratory disease, which suggested they had a subclinical, self-resolving infection.⁴⁵

59.2.2 Geographic Distribution

Blastomycosis, caused by *B. dermatitidis*, is principally a disease of North America, but it has been identified in Africa, India, Europe, and Central America. In North America, blastomycosis has a well-defined endemic distribution that includes the Mississippi, Missouri, and Ohio River valleys, the mid-Atlantic states, and the Canadian provinces of Quebec, Manitoba, and Ontario (Fig. 59-1)⁶⁶; however, the distribution may be greater than previously recognized or may be enlarging with sporadic cases in New York.^{24,26} Occupationally acquired blastomycosis was identified outside the recognized endemic area in two people from Boulder, Colo., who became infected by digging to relocate prairie dogs.^{1,26} Seven dogs with blastomycosis were reported from Colorado State University Veterinary Hospital from 1980 to 1990,⁶⁸ although the complete travel history on the animals was not available. Pets visiting or hunting in enzootic areas may become infected. Therefore the areas of risk might be greater than previously recognized. A history of travel to an endemic area should increase suspicion for blastomycosis.

570

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 59-1 Dotted lines indicate area of endemic blastomycosis. Areas of highest incidence are cross-hatched. (Courtesy University of Georgia, Athens, Ga.)

Genetic analysis of isolates from soil and human patients has resulted in three isolates—A, B, and C—and each has numerous subtypes.⁵⁸ All type A isolates were from North America in the upper Midwestern states or Canada. B and C isolates were also found in this region, the rest of the United States, and other endemic regions in the world. Genetic identification could discriminate isolated strains for epidemiologic investigations of outbreak sources and the geographic area of infection. Serologic differences in serum antibody responses were

Infectious Diseases of the Dog and Cat, 3rd Edition

found in dogs and rabbits infected with Tennessee and Wisconsin *Blastomyces* isolates, supporting regional differences in the organisms.⁵

59.2.3 Mode of Infection

Most cases of blastomycosis are acquired by inhalation of the spores from mycelial growth in the environment. The spores enter the terminal airway and establish a primary infection in the lungs. When the yeast grows at body temperature, it is too large to enter the terminal airway in an aerosol, therefore transmission by coughing is very unlikely. Inoculation of *Blastomyces* into a wound from soil appears to be uncommon in the dog, but in dogs with solitary skin infections without systemic disease the possibility of direct inoculation cannot be excluded.^{36,56} Because of the rarity of disease restricted to a focal skin area, cutaneous blastomycosis in the dog should be considered a manifestation of disseminated disease.

59.3 PATHOGENESIS

59.3.1 Host Signalment

No breed, age, or sex predisposition for blastomycosis has been recognized in the cat.⁵¹ In dogs, males are more frequently infected than females, although in a Louisiana study the male/female ratio simply reflected the clinic population.² In dogs with equally severe blastomycosis, a greater percentage of females survived treatment in one study,⁵⁵ but in another study no differences in survival were found.² An epidemiologic study using the Veterinary Medical Data Base (Purdue University, West Lafayette, Ind.) identified sporting dogs and hounds to be at greater risk for blastomycosis.⁶⁸ This finding was attributed to outdoor activity as a risk factor for developing blastomycosis, but as mentioned previously, blastomycosis also develops in strictly indoor dogs and cats.^{13,64} Many of the sporting breeds are brought to high-risk areas to hunt. Certain nonsporting breeds such as Doberman pinschers were also at increased risk.^{2,50,68} In general, large-breed dogs are more commonly infected than small-breed dogs. This finding also may reflect increased exposure from outdoor activities and roaming in larger dogs. The highest prevalence is in 2-year-old dogs; most infections develop in dogs 1 to 5 years of age. No seasonal differences in disease are found in Tennessee, but more cases occur from late spring through late fall in Wisconsin.³ In Louisiana, more cases were reported in August, September, October, and January than in the rest of the year.²

59.3.2 Dissemination of Organisms

After a *Blastomyces* infection becomes established in the lungs, it disseminates throughout the body. The preferred sites in the dog are the skin, eyes, bones, lymph nodes, subcutaneous tissues, external nares, brain, and testes. Less commonly affected sites are the mouth, nasal passages, prostate, liver, mammary gland, vulva, and heart. Intestinal lesions have rarely been found in dogs with systemic disease.^{7,62} Dissemination is thought to occur via vascular and lymphatic routes. Although organisms enter the lung in almost all cases, lung lesions may resolve by the time the sites of disseminated infection become apparent. Occasionally, a focal lesion develops from a puncture wound,^{36,56} but generally a solitary lesion should be considered part of a systemic process.

Infectious Diseases of the Dog and Cat, 3rd Edition

59.3.3 Host Response

Distinct species differences in susceptibility to *Blastomyces* seem apparent. The dog appears to be more susceptible to infection than people, and in enzootic areas of Arkansas and Wisconsin, the incidence of blastomycosis is 10 times higher in dogs than in people.^{9,14} The incidence in dogs was 1420 per 100,000 dogs per year.¹⁴ Young age and close proximity to a shoreline were risk factors.¹⁵

570

Dogs appear to have a shorter prepatent period and tend to develop the disease more quickly than people when exposed at the same time.⁷² Dogs may inhale a larger inoculum of organisms than people because they are closer to the ground. Larger doses of inoculum cause the disease to progress faster and death to occur sooner.⁸¹ The pathogenicity of isolated strains varies considerably.⁶¹ Cats rarely are infected with *Blastomyces*. A 5-year survey of the Veterinary Medical Data Program identified three infected cats, whereas 324 dogs with blastomycosis were found.⁵⁰

571

An effective immune response to *Blastomyces* requires a T-lymphocyte, cell-mediated immune (CMI) response directed partly to a surface adhesion virulence factor Wisconsin 1 (WI-1) now called *Blastomyces adhesion 1 (BAD-1) antigen*.⁴³ The BAD-1 antigen is an important virulence factor that depresses the production of tumor necrosis factor-alpha (TNF- α). TNF- α is important for phagocyte killing of the *Blastomyces* organisms and recovery from blastomycosis.^{19,28,44} Antibodies against the WI-1 antigen produced no protection against infection in a mouse model,⁸⁵ a finding that is consistent with high antibody concentrations specific for *Blastomyces* organisms in dogs with life-threatening, progressive blastomycosis. A majority of dogs *experimentally* infected by exposure to contaminated soil recover from blastomycosis without treatment.⁷⁶ It is likely that when *naturally* exposed, some dogs develop mild respiratory signs and recover spontaneously. Antibodies in 2 of 48 healthy dogs from an endemic area with no history of illness suggest that occasionally dogs do develop a subclinical, self-resolving disease.⁴⁵ However, almost all dogs with clinical signs that have warranted veterinary attention have disseminated disease and should be aggressively treated. Dogs² and people⁷¹ occasionally recover from symptomatic blastomycosis without treatment.

59.4 CLINICAL FINDINGS

59.4.1 Dogs

Dogs with blastomycosis usually have clinical signs that include anorexia, weight loss, cough, dyspnea, ocular disease, lameness, or skin lesions. Signs of disease usually have been present for a few days to a week but may have been apparent for up to a year. In some dogs the disease process seems to plateau; animals show few signs for weeks to months, but then the disease suddenly progresses and symptoms worsen. Many of the dogs have a history of antibiotic therapy with minimal or temporary improvement.

The physical findings in blastomycosis vary greatly. Mental depression is frequent but inconsistently noted. About 40% to 60% of dogs have a fever of 39.4° C (103° F) or greater. Dogs with chronic lung disease are often severely emaciated. Lymphadenomegaly of one or more lymph nodes is a common finding.

A majority (85%) of dogs with blastomycosis have lung lesions with characteristic dry, harsh lung sounds. Dogs with mild lung disease show exercise intolerance, and severely affected dogs have dyspnea at rest.

Infectious Diseases of the Dog and Cat, 3rd Edition

Coughing is a variable finding. Thoracic radiographs are indicated for dogs suspected of having blastomycosis because some dogs have lung changes without respiratory signs. On radiographs, diffuse, nodular interstitial and bronchointerstitial lung changes are the most common findings (Fig. 59-2). Other less common manifestations include well-marginated solitary to multiple cystic or solid nodules or masses. Tracheobronchial lymphadenomegaly develops in some dogs. Pleural effusion, pneumomediastinum, and cavitary lung lesions are also observed. Chylothorax and solid fibrous masses are uncommon manifestations of thoracic blastomycosis. Solid fibrous masses may partially occlude the great vessels. An obstructive anterior vena caval syndrome and *Blastomyces*-induced granulomas causing chylothorax was diagnosed in a young dachshund.³⁸ Pulmonary thromboembolism secondary to blastomycosis can increase the degree of dyspnea that develops with the fungal pneumonia.⁵⁹

Fig 59-2 Severe, diffuse miliary to nodular interstitial pulmonary infiltrate.

Fig 59-3 Panophthalmitis with associated orbital inflammation in a dog with blastomycosis. (Courtesy Diane Hendrix, University of Tennessee, Knoxville, Tenn.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Up to 40% of dogs with blastomycosis have ocular lesions, the most common of which is uveitis. Early signs of uveitis are conjunctival hyperemia, iridial hyperemia, aqueous flare, and miosis (Figs. 59-3 and 59-4). Chorioretinitis (Fig. 59-5), optic neuritis, retinal detachment, retinal granulomas, vitritis, and vitreal hemorrhage are also caused by blastomycosis. Severe corneal edema may prevent good visualization of the internal ocular structures. Glaucoma secondary to angle closure also develops.¹⁷ Lens rupture occurred in 40% of eyes with endophthalmitis requiring enucleation. The lens material probably contributed to cataract formation and ocular inflammation.³⁷ Panophthalmitis with associated orbital inflammation is common in severe ocular disease. Keratitis, conjunctivitis, and inflammation of periorbital tissues are frequently observed. A review by Krohne discusses the spectrum of lesions and specific therapy for blastomycosis in the eye.⁴⁸ Uveitis in conjunction with signs of respiratory or skin disease should alert the clinician that an animal may have blastomycosis. Early diagnosis and appropriate treatment are essential to preservation of vision in blastomycosis (see Ocular Infections, Chapter 93).

571

572

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 59-5 Chorioretinitis and retinal detachment associated with blastomycosis in a dog. (Courtesy Diane Hendrix, University of Tennessee, Knoxville, Tenn.)

Skin lesions, found in 20% to 50% of dogs with blastomycosis,^{2,49,52} may be ulcerated with drainage of a serosanguineous or purulent fluid. Other lesions may be granulomatous, proliferative, and meaty. Well-defined subcutaneous abscesses may develop. Calcinosis cutis developed in three dogs during amphotericin B (AMB) treatment.³⁴ The lesions resolved completely after the completion of treatment. Although the skin lesions may be found anywhere, the planum nasale (Fig. 59-6), the face, and the nail beds (Fig. 59-7) appear to be preferred sites.

Bone involvement occurs in up to 30% of infected dogs. Lameness is the primary sign in affected animals and may be the only sign of disease. Special procedures, such as bone scans, may identify a greater percentage of dogs with bone involvement. Lesions usually involve the appendicular skeleton and are typically osteolytic with periosteal proliferation and soft tissue swelling (Fig. 59-8). A majority of the bone lesions are solitary and develop distal to the stifle and elbow. Fungal osteomyelitis must be differentiated from primary and metastatic bone tumors and bacterial osteomyelitis.

Various other tissues may be less commonly infected, including testes, prostate, kidney, bladder, brain, mammary gland, joints, and nasal passages.^{2,49,52} The testes and epididymis may be greatly enlarged and painful. Involvement of the prostate gland produces swelling and pain. Dogs with involvement of the kidneys, bladder, or prostate may have organisms in the urine. Meningeal and secondary brain involvement usually develops with widely disseminated disease but may develop without multisystemic manifestations. Depression, seizures, and neurologic deficits are noted with central nervous system (CNS) infections. Changes in the periventricular and third ventricle area were found on contrast enhanced computed tomography (CT) imaging of the brain in a dog with CNS blastomycosis.⁶⁹ Nasal discharge and obstruction of airflow through the nose develop when blastomycosis involves the nasal passages. Lesions have been found in most organs of infected

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs. Blastomycosis of the gastrointestinal (GI) tract is rare but was identified in two dogs with generalized blastomycosis.^{7,62} Sites of *Blastomyces* infection in dogs can be identified using positron emission tomography (PET) imaging.⁵⁷ This is a very sensitive technique but unfortunately is not widely available.

Fig 59-7 Granulomatous lesion of nail bed associated with blastomycosis in a dog. (Courtesy Linda Frank, University of Tennessee, Knoxville, Tenn.)

Infectious Diseases of the Dog and Cat, 3rd Edition

59.4.2 Cats

Cats with blastomycosis have lesions similar to those of dogs, but too few cats have been evaluated to derive a reliable characterization of predominant signs. Dyspnea, visual impairment, draining skin lesions (Fig. 59-9), and weight loss have been the most frequent findings. Eye involvement generally produces a pyogranulomatous uveitis.³¹ Intracranial CNS disease and posterior paralysis also have been reported.⁶⁰ Clinical signs reflect the involved tissues: lung, lymph node, kidney, eye, CNS, skin, GI tract, pleura, and peritoneum.⁶⁰

59.5 DIAGNOSIS

59.5.1 Clinical Laboratory Testing

On preliminary laboratory evaluation, a mild normocytic, normochromic anemia develops that can be attributed to chronic inflammation. Most dogs have a moderate leukocytosis (17,000-30,000 white blood cell count [WBC]/ μ l) with a mild left shift, and lymphopenia is common. They usually have hyperglobulinemia and hypoalbuminemia. The increased globulin concentrations are caused by an increase in α_2 -globulin and a polyclonal increase in other immunoglobulins. The only other biochemical change that may be seen is hypercalcemia of granulomatous disease (12.5 to 17.5 mg/dl), which may occur without bone lesions.²⁷ Twelve of 87 dogs with blastomycosis had hypercalcemia, but the increase was less than 13.4 mg/dl in all but one dog, which had a 16.8 mg/dl increase in serum calcium.² Increased serum calcium concentrations return to normal after treatment. Hypercalcemia may be associated with renal failure.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 59-10 Budding yeast form of *Blastomyces* (new methylene blue stain, ×1260). (Courtesy University of Georgia, Athens, Ga.)

59.5.2 Organism Identification

Diagnosis should be made by identifying the organism through cytologic or histologic evaluation. Any of the common cytologic stains can be used. Because of the cost of therapy, a definitive cytologic rather than a serologic diagnosis is preferred. The combination of aspirates of enlarged lymph nodes and impression smears of skin lesions or cytology of draining exudates reveal *Blastomyces* organisms in more than half the cases (Fig. 59-10). The cytologic reaction is characteristically pyogranulomatous and include nondegenerate neutrophils and macrophages (which have an epithelioid appearance), with occasional multinucleated giant cells. Plasma cells, lymphocytes, and fibroblasts are also seen. Occasionally, a suppurative reaction predominates.³⁰ Organisms are usually plentiful in fulminating disease. When the disease is primarily ocular and less invasive diagnostic procedures have failed, vitreous aspirates or histologic examination of enucleated blind eyes can be used to diagnose the disease as blastomycosis. In dogs with productive coughs, a tracheal wash may be used to identify the organism, but this test is less reliable than other procedures, probably because of the primarily interstitial site of infection. Lung aspirates can be used when the lung is the only affected site and the results of the tracheal wash are negative. Ultrasound-guided fine needle aspirates of focal lung lesions identified organisms in five of six dogs with blastomycosis without complications.⁸² Pneumothorax is a potential complication of lung aspiration, although severe complications are uncommon. Premedication with atropine is recommended before lung aspiration to prevent excessive vagal stimulation. In dogs with urinary tract or prostatic blastomycosis, the organism may be found on urinalysis. In a dog with *Blastomyces*-induced peritonitis, peritoneal lavage recovered the organism.⁶² *Blastomyces* organisms may be found in stool samples if the organism has been coughed up and swallowed.¹² Although rare, in dogs with brain involvement, organisms may be found on examination of the cerebrospinal fluid (CSF). Culture of cytologic specimens is not recommended for in-clinic laboratories because personnel may become infected with the mycelial form of the organism (see Fig. 56-16).²⁵ The polymerase chain reaction (PCR) can be used to confirm the identity of

573

574

Infectious Diseases of the Dog and Cat, 3rd Edition

Blastomyces organisms. PCR was positive only in infected tissues in which organisms were seen on histopathologic examination.¹⁶

Atypical pulmonary fibrous masses containing organisms in small inflammatory foci may develop in lieu of the usual granulomatous reaction. These fibrous masses have few organisms, and cytology of aspirates is usually unsuccessful. Surgical biopsies are required, and multiple histologic sections with fungal staining are needed to find the organisms.

59.5.3 Serologic Testing

Only after searching for organisms should serologic testing be done to help establish a diagnosis. Although serologic testing alone is not definitive, a combination of compatible history, clinical signs, and suggestive radiographs in conjunction with positive serology tests may be substituted for identification of the organism.

The AGID test has replaced the complement fixation test and is the most commonly used serologic test for blastomycosis. It has a sensitivity of 41% to 90% and specificity of 90% to 100%.^{45,53,63} AGID test results in dogs may be negative early in the development of infections. A positive AGID result is strongly supportive of *but not* definitive for blastomycosis. The AGID test has been used in only a few infected cats, and results were positive in only one of three cats tested.⁶⁰ Although the intensity and the number of bands seen on the AGID tend to decrease after successful treatment, the persistence of antibodies in cured animals precludes AGID for evaluating response to therapy or recurrence of disease. An RIA for detecting antibodies against *Blastomyces* was more sensitive than the AGID, detecting 92% of infected dogs, whereas the AGID detected 41%.⁴⁵ Enzyme-linked immunosorbent assay (ELISA) methods using *B. dermatitidis* have also been developed^{6,23}; however, their accuracy and sensitivity have not been as extensively evaluated. (See [Appendix 5](#) for a listing of laboratories that offer this test.)

Table 59-1 Drug Therapy for Blastomycosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION ^c (DAYS)
Itraconazole (ITZ)	Dog ^d	5	PO	24	60
	Cat	5	PO	12	60
Fluconazole (FCZ)	Dog	5	PO	12	60
Amphotericin B (AMB)	Dog	1	IV	3 times weekly	Varies ^f
lipid complex ^e AMB	Dog	0.5	IV	3 times weekly	Varies ^g
	Cat	0.25	IV	3 times weekly	Varies ^h

PO, By mouth; IV, intravenous.

- a See text and Drug Formulary, [Appendix 8](#), for additional information concerning administration of each drug.
- b Dose per administration at specified interval.
- c Minimum duration of therapy. Ideally, therapy should continue for at least 1 month beyond the last detection of clinical illness or infection.
- d ITZ is preferred drug and dosage therapy. ITZ should be given every 12 hours for the first 5 days (see text). A 12-hour interval (10 mg/kg/day

Infectious Diseases of the Dog and Cat, 3rd Edition

- e Three lipid formulations are available (see Drug Formulary, [Appendix 8](#)). Efficacy at this dose has been established for ABLC (Abelcet,
- f Stop when cumulative dose reaches 12 mg/kg.
- g Stop when azotemic or cumulative dose reaches 4–6 mg/kg, then start azole, or when cumulative dose is 8–10 mg/kg when given alone.
- h Stop when azotemic or cumulative dose reaches 4 mg/kg, then use ITZ.

59.6 PATHOLOGIC FINDINGS

Blastomyces produces purulent to pyogranulomatous lesions in infected tissues of dogs and cats. The yeasts are admixed with neutrophils, macrophages, and multinucleated giant cells. Lymph nodes are hyperplastic and have increased numbers of plasma cells and macrophages. In tissue, the broad-based, budding yeasts are best seen with special stains, such as periodic acid–Schiff, Gridley's fungal, or Gomori's methenamine silver stain. Filamentous forms rather than the yeast form have been found in the tissue of people and dogs,⁴² and giant forms of the organism measuring 30 to 35 μm in diameter rather than the usual 20 μm have been seen.⁴⁰ *Blastomyces* organisms in the eyes are primarily found in the choroid and rarely in the retina or anterior segment.²²

59.7 THERAPY

For a summary of the dosage regimens, see [Table 59-1](#) (and the Drug Formulary, [Appendix 8](#), for additional information).

59.7.1 Amphotericin B

AMB is an effective, rapidly acting, fungicidal drug for the treatment of various systemic fungal infections, including blastomycosis. Because AMB is nephrotoxic and has to be given intravenously (IV), it has been replaced as the drug of choice for blastomycosis by itraconazole (ITZ), which is equally effective and safer.⁵⁴ (See Drug Formulary, [Appendix 8](#), for additional information on AMB and its precautions.)

In dogs that cannot absorb oral medications or have not responded to ITZ treatment, AMB can be a life-saving drug. AMB deoxycholate should be given at a dose of 0.5 mg/kg every other day. The serum urea concentration should be monitored closely and the AMB discontinued when the urea level approaches 50 mg/dl. A cumulative dose of 8 to 10 mg/kg is required to cure blastomycosis. Cats should be given no more than 0.25 mg/kg every other day.

AMB lipid complex (see Drug Formulary, [Appendix 8](#)) has been less toxic when given to treat dogs with systemic blastomycosis.⁴⁷ The effective dose is somewhat higher than that of AMB deoxycholate and it is considerably more expensive, but the drug is much less nephrotoxic. Unless the dog has preexisting renal disease, it is difficult to justify the high cost of the lipid complex AMB as the initial treatment with AMB.

Infectious Diseases of the Dog and Cat, 3rd Edition

59.7.2 Itraconazole

59.7.2.1 Dogs

ITZ is an azole drug of the triazole group (see Drug Formulary, [Appendix 8](#)). Dogs with blastomycosis respond to treatment with ITZ as rapidly as they do with AMB and more rapidly than they do with ketoconazole (KTZ). Compared with AMB, ITZ is easier to administer and has fewer side effects. Because ITZ is given orally, dogs can be treated at home. Although ITZ is more costly than AMB, the cost of treatment with ITZ is similar if the expense of IV administration and frequent monitoring of renal function with AMB is considered. Dogs that cannot take oral medications can receive an IV form of ITZ; however, it is expensive.

Seventy-four percent of dogs treated with 5 mg/kg/day of ITZ responded to treatment; a 77% response rate was found in a historic control group treated with AMB.⁵⁴ Of the dogs that responded initially, 20% of the AMB-treated dogs and 20% of the ITZ-treated dogs had a recurrence of disease after completing the ITZ treatment.⁵⁴ Likewise, in another study, 21 of 31 dogs (68%) responded to a 60- to 90-day course of ITZ. In responding dogs, 5 of 21 dogs (24%) had a recurrence, and 4 of those dogs were successfully retreated with a second course of ITZ.² The mortality rates of ITZ-treated and AMB-treated dogs are very similar. The 5 mg/kg/day dose of ITZ is better than the 10 mg/kg/day dose. The cure and relapse rates are similar, but the lower dose group had fewer adverse effects. ITZ appears to penetrate the eye in dogs with active disease, because the dogs with ocular blastomycosis of the posterior chamber often respond to ITZ treatment.²⁰

Twice-daily dosing with 5 mg/kg has been recommended for intraocular infections.³² Variconazole, a related azole, has been effective in treating CNS blastomycosis in a person.^{6a} ITZ is not excreted in the urine, so it cannot be used in urinary tract disease. Fluconazole (FCZ) is excreted in the urine and should be considered in these cases. The ease of administration, the decreased likelihood of toxicity, and the efficacy of ITZ make it the drug of choice for the treatment of blastomycosis. The only disadvantage of ITZ treatment is the relatively high cost of the drug.

For dogs, ITZ should be started at a dosage of 5 mg/kg every 12 hours for 5 days to maximize blood concentrations rapidly. The dosage is then reduced to 5 mg/kg/day for the remainder of the treatment. ITZ treatment should be continued for at least 60 days and for at least 1 month after all signs of disease have resolved. Most dogs with mild to moderate lung involvement can be cured with a 60-day course of treatment. Dogs with severe lung involvement should be treated for at least 90 days. Recurrence occurs in about 20% of responding dogs—usually within 1 year of treatment completion. FCZ can be used for the treatment of blastomycosis but it is not as effective as ITZ. (See Drug Formulary, [Appendix 8](#), for additional information on ITZ.)

59.7.2.2 Cats

Cats with blastomycosis have been successfully treated with ITZ at 5 mg/kg given every 12 hours. This is an effective, safe treatment for most cats. No studies have been done on the efficacy of lower drug dosages.

Infectious Diseases of the Dog and Cat, 3rd Edition

59.7.2.3 Adverse Effects

The most common adverse effect of ITZ treatment is anorexia associated with hepatotoxicity. Ninety-two percent of dogs receiving 5 mg/kg/day had no clinical signs of toxicity.⁵⁴ Only 1 of 24 dogs studied had serum ALT activities above 200 U/L. Increases in liver enzymes correlate with serum concentrations of ITZ. Serum concentrations of ITZ can vary tremendously in dogs receiving the same dose of drug. If toxicity occurs, medication should be stopped until the appetite returns and the serum liver enzyme activities return to less than 100 U/L. The medication should be reinstituted at half the former dose and serum liver enzymes monitored every 2 weeks.

Ulcerative dermatitis developed in 7.5% of dogs receiving 10 mg/kg/day of ITZ, but it did not develop in any dog receiving 5 mg/kg/day (Fig. 59-11).⁵⁴ Ulcers were usually focal, 1 to 2.5 cm in diameter, and circular, with ischemic dermis from an underlying vasculitis. The lesions healed quickly after ITZ was stopped. Lesions did not recur when ITZ was restarted at a decreased dose. This reaction must not be interpreted as a recurrence of blastomycosis.

Serum concentration of ITZ can be measured to ensure that the dog is receiving enough drug.⁵⁴ Serum ITZ concentrations of 2 µg/ml or greater appear to be adequate. Serum samples can be sent to the Fungus Testing Lab, University of Texas Health Science Center, 7703 Floyd Curl Drive, San Antonio, TX 78284.

59.7.3 Prognosis

The prognosis for dogs and cats with blastomycosis is good. One way to monitor response to therapy is to perform follow-up thoracic radiography of treated animals after clinical remission (Fig. 59-12). The two prognostic factors for survival are brain involvement and severity of lung disease. Dogs with brain involvement usually die but occasionally can be treated successfully. Dogs with CNS signs should be treated initially with AMB. The severity of lung infiltrates may worsen in the first 2 to 3 days of treatment, and the worsening of signs has been attributed to an inflammatory response to dying organisms in the lungs. Death usually results from respiratory failure and occurs in 50% of the dogs with severe lung disease during the first 7 days of treatment. Dexamethasone at a dose of 0.25 to 0.5 mg/kg IV for 2 to 3 days can be given to dogs that develop life-threatening respiratory disease after starting antifungal treatment. The glucocorticoids must only be given in conjunction with antifungal treatment. This should reduce the inflammatory response in the lung enough to avoid respiratory failure. Dogs that receive glucocorticoids should be treated for at least 90 days with antifungal drugs. Improved survival rates can be achieved only with earlier diagnosis of the condition before severe lung disease occurs. For ocular lesions, dogs with mild posterior segment disease, without complete retinal separation, have good prognoses for retaining vision.¹⁷ Dogs with severely affected eyes with endophthalmitis, glaucoma, or both have poor prognoses for improvement in vision.^{48,49,52}

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 59-11 Ulcerative dermatitis may occur in some dogs treated with 10 mg/kg/day of itraconazole. (From Legendre AM, Rohrbach BW, Toal RL. Treatment of blastomycosis with itraconazole in 112 dogs. *J Vet Intern Med* 10:365-371, 1996.)

Fig 59-12 Thoracic radiographs from dog with blastomycosis. **A**, Before treatment. **B**, After therapy, showing reduced pulmonary alveolar-interstitial density. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Budding, apparently viable, *Blastomyces* organisms were found in 85% of enucleated, blind eyes despite ITZ treatment.³⁷ Blind eyes should be enucleated after the animal can safely tolerate anesthesia to eliminate a persistent focus of infection.

59.7.4 Treatment of Relapse

Approximately 20% to 25% of the dogs relapse after treatment with ITZ, AMB alone, or AMB plus KTZ treatment.^{2,54,55} Recurrence after apparently successful treatment usually occurs in the first 6 months after completion of therapy, but recurrences can occur up to 3 years after completion of therapy.^{2,54,55} Likelihood of relapse is related to severity of the initial lung disease. Reinfection after successful treatment does not appear to occur, and the recurrence of infection is probably a result of reactivation of a residual site of infection. Recurrence of disease can be effectively treated with another 60- to 90-day course of ITZ. The *Blastomyces* organisms do not appear to develop resistance to the ITZ. Retreatment has an 80% or greater chance of producing a cure.

59.8 PREVENTION

The ecologic niche for growth of *Blastomyces* has not been identified, therefore preventive measures are impossible. Even if the site were identified, sterilization of the soil is impossible. Restricting animals from lakes and creeks in areas where other dogs have become infected may be helpful. Dogs should be kept away from construction sites where people have been digging. Dogs kennelled in a heavily shaded area where the soil remains moist may be at increased risk. Removal of some tree branches to allow sunshine into the kennel area may be helpful in reducing the risk of infection. A potential modified live vaccine for prevention of blastomycosis has been developed by deletion of the WI-1 or BAD-1 virulence factor gene. This modified organism protects mice against challenge with *Blastomyces* organisms.^{83,84} This potential vaccine needs to be evaluated in dogs.

59.9 PUBLIC HEALTH CONSIDERATIONS

The yeast phase of the organism cannot be transmitted from animals to people or from people to people through aerosols. Penetrating wounds by objects contaminated by the organism have produced infections in people.³⁶ Care should be taken to avoid bites when handling a dog with blastomycosis.³³ Contaminated knives or needles can accidentally inoculate clinicians during necropsy or fine-needle aspiration.^{35,65} The organism should be cultured only in laboratories with proper facilities. Primary pulmonary blastomycosis has readily developed in laboratory workers exposed to cultures of the mycelial form of *B. dermatitidis*.^{8,25}

60 CHAPTER 60 Histoplasmosis

Craig E. Greene

60.1 ETIOLOGY

The etiologic agent of American histoplasmosis is the soil-borne, dimorphic fungus *Histoplasma capsulatum*. This organism can survive wide fluctuations in environmental temperature and prefers areas with warm (mean ambient temperatures of 22° C to 29° C [71° F to 84.2° F]) moist (annual precipitation 35 to 50 inches), and humid (67% to 87%) conditions. These conditions are generally between latitudes 45 degrees north and 30 degrees south. *H. capsulatum* grows best and accelerates its sporulation in soil containing nitrogen-rich organic matter such as bird and bat excrement. Although most affected animals have exposure to the outdoor environment, some affected cats have been housed exclusively indoors. This finding suggests that even accumulations of household dust or soil-containing houseplants may be potential sources of infection.

60.2 EPIDEMIOLOGY

H. capsulatum is endemic throughout large areas of the temperate and subtropical regions of the world (Fig. 60-1). Although infections have been documented from every continent except Antarctica, they are most prevalent in the Americas, India, and southeastern Asia. Infection has been documented in dogs in Japan.^{26,43} The organism in these infections may be *H. capsulatum* var. *farcinosum*. The organism *H. capsulatum* var. *duboisii*, the cause of African histoplasmosis, is confined to that continent, while *H. capsulatum* var. *capsulatum* (*H. capsulatum*) has been isolated from soil in 31 of the continental United States. Most clinical cases occur in the central United States in the region of the Ohio, Missouri, and Mississippi Rivers. Histoplasmosis can appear in traditionally nonendemic regions if local environmental conditions are altered to favor fungal growth. Soil rich in bird or bat feces, such as where poultry is raised or in caves, respectively, is most likely to harbor the fungus. Obtaining a detailed travel history is important to identify patients that may have acquired infection while in endemic regions.^{19,25a}

Determining true rates for histoplasmosis in companion animals is difficult because most infections are subclinical. The prevalence of infection probably parallels that in the human population in endemic regions.

60.3 PATHOGENESIS

The life cycle of *H. capsulatum* is similar to that of other dimorphic fungi. The free-living, environmentally resistant mycelial stage in soil at 25° C (77° F) produces macroconidia (5 to 18 µm) (see Fig. 56-15) and microconidia (2 to 5 µm) that are the source of infection for mammals. Histoplasmosis is probably acquired by inhalation of microconidia that are small enough to reach the lower respiratory tract. The incubation period after exposure in susceptible hosts is approximately 12 to 16 days.¹⁵ In the body at 37° C, the microconidia convert to the yeast phase in the lung and reproduce by budding. The yeast organisms are phagocytized by cells of the host's mononuclear phagocyte system and undergo further intracellular replication. Infection may be grossly limited to the pulmonary tree; however, lymphatic and hematogenous dissemination of *H. capsulatum* can occur early in the course of the disease because of the intracellular location of the fungus. Severe clinical disease can result if the dose of infective spores is large or if the immune system of the host is compromised. The cellular immune system, predominantly involving cytokine-mediated macrophage killing, will rapidly bring the infection under control in most patients. T-cell immunity is critical for clearance of the organism. In immunocompetent hosts, *H. capsulatum*

Infectious Diseases of the Dog and Cat, 3rd Edition

may establish a dormant phase and may not be totally eliminated from the mononuclear phagocyte system.¹⁶ With subsequent immunosuppression, reactivation of infection can occur. Dissemination involves primarily organs that are rich in mononuclear phagocytes.

The yeast form of *H. capsulatum* may be more resistant to host defense mechanisms because it is more invasive. Only in endocarditis does the mycelial form sometimes appear on the valve leaflets. When conidia are incubated at 34° to 37° C, genes producing heat shock proteins 70 and 83, M-phase cell cycle enzymes, and tubulin proteins are activated. The walls of yeasts contain more chitin and less mannose and amino acids than do mycelial-phase cells. These transformed yeasts readily enter the cytoplasm of phagocytes where they are engulfed by phagolysosomes. The yeasts raise the intracellular pH slightly by releasing urease, ammonia, and bicarbonate, thus facilitating their absorption of intracellular iron.

In addition to phagocyte impairment, the fungus induces nonspecific anergy, as demonstrated in people and mice with disseminated infections. The yeast cells overproduce interleukin (IL)-4, which at high levels can interfere with the cellular immune response. The yeast also synthesizes melanin or melanin-like compounds, as do other pathogenic yeasts, and this may be an important virulence factor.³⁷

The occurrence of gastrointestinal (GI) histoplasmosis without respiratory tract involvement suggests that the GI tract may also be a primary site of infection. However, experimental studies have failed to produce GI disease reliably after oral administration of *H. capsulatum* spores.

60.4 CLINICAL FINDINGS

60.4.1 Cats

Cats are very susceptible hosts and are at least as likely as dogs are to develop clinical histoplasmosis. The age range of cats affected with histoplasmosis is 4 months to 14 years; the majority of cases occur in young cats (under 4 years).²⁴ No apparent breed predilection is present; females appear to be more commonly affected than are males.²⁴

577

578

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 60-1 The prevalence of histoplasmosis in North and South America based on seropositivity in people. The darker-shaded areas indicate zones of very high endemicity. (Courtesy University of Georgia, Athens, Ga.)

Most infected cats have disseminated disease and exhibit a wide range of nonspecific clinical signs, including depression, weight loss, fever, anorexia, and pale mucous membranes.¹⁰ Coughing is uncommon, but dyspnea, tachypnea, and abnormal lung sounds are found in more than one half of affected cats. Other frequent findings include peripheral or visceral lymphadenomegaly, splenomegaly, and hepatomegaly. Occasionally, *Histoplasma* infects the eye, causing conjunctivitis, granulomatous blepharitis, granulomatous chorioretinitis,

Infectious Diseases of the Dog and Cat, 3rd Edition

retinal detachment, and optic neuritis.^{24,25,34} Some cats have had osseous lesions, causing soft-tissue swelling and lameness. The skin is infrequently affected with nodular or ulcerated lesions.³⁸ Rare clinical findings include oral ulcers, nasal polyps, vomiting, and diarrhea.

60.4.2 Dogs

Histoplasmosis has been reported in dogs ranging in age from 2 months to 14 years. Most affected dogs are young (under 4 years), and no apparent sex predilection is present. Pointers, Weimaraners, and Brittany spaniels are overrepresented in some published reports.^{2,51,52}

Fig 60-2 Dog with severe weight loss caused by malabsorption from *Histoplasma* enteritis. (Courtesy University of Georgia, Athens, Ga.)

Inappetence, weight loss, and fever unresponsive to antibiotic therapy occur in most cases of canine histoplasmosis (Fig. 60-2). In some dogs, the clinical signs may be limited to the respiratory tree and include dyspnea, coughing, and abnormal lung sounds. However, in most dogs, clinical signs result from disseminated

Infectious Diseases of the Dog and Cat, 3rd Edition

histoplasmosis with GI involvement.^{11,30} Signs of large-bowel diarrhea with tenesmus, mucus, and fresh blood in the stool are the most common clinical findings. Pale mucous membranes often are found in patients with bone marrow involvement or GI blood loss. Extensive *Histoplasma* infiltration of the small bowel can cause a voluminous, watery stool with an accompanying protein-losing enteropathy (Fig. 60-3). Hepatomegaly, visceral lymphadenomegaly, splenomegaly, icterus, and ascites are frequent associated findings. Unusual signs include vomiting, peripheral lymphadenomegaly, and lameness as a result of osseous infection. Ocular lesions and skin lesions as described for cats have also been reported in the dog. Neurologic involvement, recognized with dissemination of infection in dogs, is rare.³⁶ Lesions in infected dogs from Japan have been confined to the skin or gingival, and pulmonary or GI lesions have not been grossly apparent.²⁶

60.5 DIAGNOSIS

60.5.1 Clinical Laboratory Findings

The most common hematologic abnormality in both dogs and cats with disseminated histoplasmosis is normocytic, normochromic, nonregenerative anemia. The anemia probably results from chronic inflammatory disease, *Histoplasma* infection of the bone marrow, and intestinal blood loss in GI disease. Leukocyte counts are variable. Neutrophilic leukocytosis with monocytosis and eosinopenia is found most frequently. Leukopenia and thrombocytopenia have also been reported. In a survey of neutropenic dogs, histoplasmosis was associated as a risk factor.⁶ Severe pancytopenia has been observed in some cats. *Histoplasma* organisms may be found during routine blood film examination in circulating monocytes, neutrophils, and, rarely, eosinophils. Performing 1000-cell differential counts or examining buffy coat smears will enhance detection of infected cells.

Fig 60-3 Severe watery diarrhea from malabsorption found in the dog in Figure 60-2. (Courtesy University of Georgia, Athens, Ga.)

Abnormal coagulation function tests have been found in some thrombocytopenic dogs with disseminated histoplasmosis, suggesting the presence of microangiopathic hemolysis. Disseminated intravascular coagulation

Infectious Diseases of the Dog and Cat, 3rd Edition

(DIC) in these dogs may occur as a result of extensive *Histoplasma* infiltration of the liver. Hemolysis and an increased bleeding tendency associated with DIC may enhance the severity of the anemia in these patients.

Biochemical profiles are usually unremarkable in dogs with pulmonary histoplasmosis. Hypoalbuminemia is a fairly consistent finding in cats with disseminated histoplasmosis. Some cats have had hyperproteinemia, hyperglobulinemia, and mild elevations of serum glucose and alanine aminotransferase (ALT) activities. Dogs with disseminated disease may have hypoproteinemia and severe hypoalbuminemia as a result of intestinal blood loss or protein-losing enteropathy. Liver dysfunction in affected dogs may cause hypoalbuminemia, hyperbilirubinemia, elevated serum alkaline phosphatase and ALT values, and abnormal results on liver function tests.⁷ Hypercalcemia (probably associated with granulomatous disease) has been reported in several cats.²⁴

Urinalyses are usually normal in dogs and cats with histoplasmosis. Most cats have tested negative for feline leukemia virus and feline immunodeficiency virus infections.

60.5.1.1

Radiography and Ultrasonography

Thoracic radiographs of dogs and cats with active pulmonary histoplasmosis usually exhibit a linear or diffuse pulmonary interstitial pattern associated with granulomatous fungal pneumonia (Fig. 60-4, A). The infiltrates often are coalescing and may appear miliary or grossly nodular. True alveolar involvement in pulmonary histoplasmosis is rare. Hilar lymphadenomegaly is common in dogs but rare in cats (see Fig. 60-4, B). Pleural effusion occurs infrequently in the dog. Pulmonary calcification, indicative of inactive pulmonary histoplasmosis, is occasionally seen in dogs.

The interpretation of abdominal radiographs in dogs with GI histoplasmosis may be difficult because of the emaciated condition of the patient or the presence of abdominal fluid. Noncontrast studies may demonstrate hepatomegaly, splenomegaly, or ascites (Fig. 60-5). Barium contrast examination may reveal irregularities of the intestinal mucosa and thickening of the intestinal walls.

Fig 60-4 A, Lateral radiograph of a *Histoplasma*-infected dog with tracheobronchial lymphadenomegaly and linear nodular diffuse interstitial infiltrates. B, Lungs from a 2-year-old domestic shorthaired cat that died from widespread, fulminating, granulomatous pneumonia caused by *H. capsulatum*. (Part A courtesy Department of Radiology, University of Georgia, Athens, Ga.; Part B courtesy Alice Wolf, Texas A&M University, College Station, Tex.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Ultrasound examination of dogs with liver involvement reveals hyperechoic liver parenchyma (Fig. 60-6).⁷ Nodular and infarctive lesions have also been observed.

Osseous involvement with histoplasmosis is rare in the cat and even less common in the dog. The typical radiographic appearance of bony lesions is a mixed pattern of osteolysis, subperiosteal bone proliferation, and periosteal new bone formation (Fig. 60-7). Intraarticular infection has been observed in both dogs and cats but is rare.²⁵ In the cat, *Histoplasma* most frequently infects the metaphyses of long bones with a predilection for the bones of and adjacent to the carpal and tarsal joints.

60.5.2 Endoscopy

Endoscopic examination of dogs with colonic histoplasmosis reveals mucosal thickening, granularity, friability, and ulceration.³⁰ Cytologic or histologic examination of rectal scrapings and biopsy samples usually reveals large numbers of *Histoplasma* organisms.

60.5.2.1 Transtracheal Wash and Bronchoalveolar Lavage

Transtracheal wash (TTW) and bronchoalveolar lavage (BAL) have been suggested as methods to evaluate patients with suspected pulmonary mycotic infections in which organisms were not recovered by other noninvasive methods.²² Generally, BAL is superior to TTW because the collected cells are more representative of the interstitial and distal portions of the airway. BAL requires anesthesia and causes more respiratory compromise than does TTW; therefore patients must be evaluated carefully before undergoing this procedure. Fungal organisms may not be numerous in specimens recovered with either procedure, and the sensitivity of these tests has not been thoroughly evaluated.

60.5.3 Cytologic and Histologic Findings

Histoplasma organisms are usually numerous in infected tissues. A definitive diagnosis can often be made by fine-needle aspiration and exfoliative cytology.³⁸ The organisms are usually contained within cells of the mononuclear phagocyte system; single or multiple yeast cells may be present within each phagocytic cell. Routine Wright or Giemsa's hematologic stains demonstrate the organism as a small (2 to 4 μ m) round body with a basophilic center and lighter halo caused by shrinkage of the yeast during staining (Fig. 60-8). In the cat, *Histoplasma* organisms are most easily recovered from bone marrow, lung, and lymph node aspirates. Rectal scrapings, imprints of colonic biopsy specimens, and aspirates of liver, lung, spleen, and bone marrow are most productive in the dog. *Histoplasma* organisms have been found in macrophages in peritoneal and pleural effusions, and these and other tissues should be examined as warranted by the clinical signs in each case.²⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 60-8 *H. capsulatum* in circulating blood monocytes. This organism can also be found in neutrophils and, rarely, in eosinophils (Wright, ×1000). (Courtesy Ken Latimer, University of Georgia, Athens, Ga.)

Tissue biopsy may be required if exfoliative cytology is not diagnostic. Affected tissues demonstrate granulomatous inflammation, but *Histoplasma* organisms are difficult to detect with routine hematoxylin and eosin stain. Special fungal stains (periodic acid-Schiff, Gomori's methenamine silver, Gridley's fungal stain) should be used to enhance detection of the organisms if histoplasmosis is suspected. Immunostaining with polyclonal anti-*Mycobacterium bovis* (Bacille Calmette-Guérin) was used to identify *Histoplasma* and other infectious agents in skin biopsy specimens in animals.⁴

60.5.3.1 Cerebrospinal Fluid

Central nervous system (CNS) involvement is rare in dogs or cats with histoplasmosis. Cerebrospinal fluid (CSF) specimens from affected dogs demonstrate increased protein and cellularity.³⁶ The granulomatous cellular response consists of nondegenerate neutrophils, macrophages, monocytes, and occasional lymphocytes. *Histoplasma* organisms have been identified in CSF macrophages in some patients.

60.5.4 Fungal Isolation

Attempts to culture *H. capsulatum* in a routine practice setting are *not* recommended because of the pathogenic potential of this organism. *H. capsulatum* can be cultured from tissue specimens, fine-needle aspirates, and body fluids. The yeast phase produces white, moist colonies when inoculated on blood agar and incubated at 30° or 37° C (see [Chapter 56](#) and [Fig. 56-15](#)). The mycelial phase will develop within 7 to 10 days on routine fungal culture media incubated at room temperature. Microconidia produced by the mycelial phase are infectious, and cultures exhibiting fluffy white or buff-brown mycelial growth should be handled with caution.

Infectious Diseases of the Dog and Cat, 3rd Edition

60.5.5 Immunodiagnosis

Intradermal skin tests for reactivity to histoplasmin are unreliable in companion animals and cannot be used to confirm the diagnosis of histoplasmosis. Serologic tests (agar-gel immunodiffusion, complement fixation) for antibodies directed against *Histoplasma* antigens are often falsely negative in animals with active naturally occurring disease.^{24,28} Test results may be false positive in an animal with prior exposure that has recovered from infection. Sera from dogs with histoplasmosis cross-react with *Blastomyces dermatitidis* antigens used in enzyme-linked immunosorbent assay (ELISA) for detection of antibodies.⁴⁵ Currently, no consistently reliable antibody detection test is available for identification of histoplasmosis in companion animals.

An antigen detection assay, which identifies a polysaccharide antigen of *H. capsulatum* in serum, CSF, or urine, has been used in the diagnosis of human infections^{46a} (MiraVista Diagnostics, Indianapolis, Ind.; <http://www.miravistalabs.com>; see Appendix 6). This assay has become important in the monitoring of immunosuppressed people because it gives generally 90% positive results in patients with progressive disseminated histoplasmosis. Positive rates are much lower with confined pulmonary lesions. Antigen concentrations decrease during therapy, and increases have been correlated with relapses.⁴⁷ Even in human infections, cross-reactivity of the urine test for *Histoplasma* antigens occurs in people with blastomycosis, coccidioidomycosis, and penicilliosis.⁴⁸ The test might be of value as a provisional diagnostic aid for animals with serious infections caused by one of these organisms; however, further studies are needed.

Polymerase chain reaction (PCR) has been used on a limited basis in diagnosis of human infections. Infection was confirmed in one dog by nested PCR on paraffin-embedded biopsy specimens.⁴³ PCR has also been used to examine different strains in soil and those from corresponding human and canine infections in the same geographic region.¹⁷

60.6 PATHOLOGIC FINDINGS

The organs affected in histoplasmosis will depend on whether the disease is pulmonary or disseminated. In the pulmonary form, the lesion can be active, with miliary or larger gray foci, or chronic and calcified. With dissemination, many visceral organs are generally involved. The surface of the intestinal tract is thickened and the mucosa often hemorrhagic (Fig. 60-9). The liver is enlarged and has a variegated pale pattern resulting from inflammatory infiltration (Fig. 60-10). With disseminated disease, many parenchymal organs are affected. The hilar and mediastinal lymph nodes may be grossly enlarged and firm (Fig. 60-11). This enlargement may be sufficient enough to cause tracheal or vascular compression. Histologically, granulomatous nodules are infiltrated by macrophages containing *Histoplasma* organisms. *Histoplasma* organisms may be difficult to visualize (Fig. 60-12). Neutrophils are often seen in close association, and occasional infiltration with lymphocytes and plasma cells can be observed. Within the lungs, interstitial and peribronchial thickening can encroach on and fill alveoli.

60.7 THERAPY

60.7.1 Antifungal Drugs

Pulmonary histoplasmosis in the dog may be self-limiting and can resolve without treatment.¹⁵ However, antifungal chemotherapy is recommended because dissemination can occur early in the course of infection (Table 60-1). Itraconazole (ITZ) is currently the drug of choice for the treatment of histoplasmosis in animals. Treatment is usually initiated once daily; however, pharmacokinetic studies in cats indicate significant variability in the oral absorption of ITZ, and twice daily dosing (at 10 mg/kg) may be required in some cats to achieve the desired therapeutic effect.⁵ The oral solution is more consistently absorbed, when compared with capsules, allowing for 10 mg/kg once daily dosing. See Drug Formulary, Appendix 8, for detailed information on the use of ITZ.

Table 60-1 Therapy for Histoplasmosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION (MONTHS)
Itraconazole	B	10	PO	12–24	4–6 ^c
Ketoconazole	D	10–20	PO	12	4–6
AMB ^d	B	0.25–0.5	IV	48 ^e	^f

B, Both dog and cat; D, dog; AMB, amphotericin B; PO, by mouth; IV, intravenous.

a See Drug Formulary (Appendix 8) for further information.

b Dose per administration at specified interval.

c Minimum time; each case must be evaluated independently; see text. Treat for at least 2 months after resolution of clinical signs.

Infectious Diseases of the Dog and Cat, 3rd Edition

- d Given in conjunction with a concurrently administered oral azole. See [Table 57-2](#) and Drug Formulary, [Appendix 8](#), for alternate formulations and dosages of AMB.
- e Monday-Wednesday-Friday schedule usually used.
- f Continue until cumulative dose of 5 to 10 mg/kg is reached in dogs, 4 to 8 mg/kg in cats.

Despite the reportedly poor penetration of ITZ into the CNS and eye, several cats with *Histoplasma*-induced ocular lesions had complete resolution of disease with a standard course of ITZ therapy.^{24,53} Liposomal amphotericin B (AMB) has been used to treat people with CNS histoplasmosis.^{46a}

In dogs or cats with severe or fulminating pulmonary or GI histoplasmosis with dissemination, AMB or combination therapy with AMB and ITZ or high loading doses of ITZ may provide more rapid control of the fungal infection (see [Table 60-1](#)). See the Drug Formulary, [Appendix 8](#), for further information on AMB. ITZ treatment is initiated simultaneously with AMB administration and is continued after termination of the AMB regimen.

The duration of antifungal treatment required for each patient is variable and is determined by the severity of infection and the patient's clinical response. The response to therapy should be evaluated by monitoring for the resolution of clinical signs, hematologic and biochemical abnormalities, and radiographic lesions. Generally, most patients are treated with oral antifungal drugs for at least 4 to 6 months.

582

583

Fig 60-12 Many intracellular *Histoplasma* organisms in a tissue biopsy specimen from a dog with disseminated histoplasmosis (PAS, ×400). (Courtesy University of Georgia, Athens, Ga.)

Another orally administered triazole, fluconazole (FCZ), has better penetration into the CNS and eye than does ITZ (see Drug Formulary, [Appendix 8](#)). FCZ is theoretically preferred for patients with neurologic involvement or ocular lesions that are refractory to AMB or ITZ treatment. FCZ may also be used for animals that do not tolerate ITZ therapy; however, it is not as effective as ITZ is in treating people with histoplasmosis.³⁵ Similar

Infectious Diseases of the Dog and Cat, 3rd Edition

studies in animals outlined later indicate that FCZ is not very effective in the treatment of histoplasmosis. FCZ but not ITZ antagonized the effectiveness of AMB when these combinations were used to treat mice with disseminated histoplasmosis.³¹ In mice with experimental *Histoplasma* meningitis, FCZ monotherapy and AMB and FCZ combined therapy was less effective compared with AMB monotherapy.²³ Therefore FCZ is not recommended over AMB or ITZ for treatment of histoplasmosis. ITZ has been effective in treating CNS histoplasmosis in people in which AMB and FCZ treatment have failed.¹ ITZ is more active than FCZ is against *H. capsulatum* in vitro, which parallels its superior in vivo effectiveness. Although concentrations of ITZ in CSF are negligible, those in CNS tissue exceed that in plasma and may explain the benefits of this drug in treating CNS mycoses.

Ketoconazole (KTZ), the first licensed oral azole antifungal agent, has lower potency against *Histoplasma* and increased relative toxicity compared with ITZ and FCZ. For these reasons, it is not recommended as a first-choice treatment unless expense becomes a limiting factor. See Drug Formulary ([Appendix 8](#)) for further information.

Voriconazole is active against *Histoplasma* and penetrates the CSF, making it a consideration for treating CNS infection. Posaconazole (PCZ, SCH 56592) is a newer triazole structurally related to ITZ. It was shown to be highly effective when compared to AMB or ITZ in treating immunosuppressed mice with disseminated histoplasmosis.¹²

The ability to treat animals with histoplasmosis effectively has improved significantly because of the availability of safe and efficacious oral azole antifungal drugs. Dogs and cats with pulmonary histoplasmosis have a fair to excellent prognosis. The prognosis for animals with disseminated histoplasmosis is fair to good, depending on the severity of fungal involvement. *Histoplasma*-infected areas most difficult to treat with histoplasmosis are CNS, ocular, bony, and epididymal infections. For the epididymal infections, orchiectomy is advised. For the others, prolonged antifungal therapy is needed, although the prognosis for complete recovery is guarded. The prognosis for return of vision depends on the severity of retinal damage before the control of infection.^{20,29}

60.7.2

Antiinflammatory Drugs

Life-threatening infection with histoplasmosis is caused by rapid proliferation of the organism in many tissues, including the lung, and from chronic airway obstruction from hilar lymphadenomegaly. Glucocorticoids have been used to treat people with active inflammatory disease and chronic airway obstruction. Clinical signs and airway obstruction associated with hilar lymphadenomegaly resolved more rapidly in dogs treated with glucocorticoids with or without antifungal chemotherapy.⁴² Coughing decreased more rapidly, and the glucocorticoid-treated animals had improvement in their overall well being. Clinical improvement was noted in a mean of less than 1 week, 2.6 weeks, and 8.8 weeks, in dogs with suspected chronic pulmonary histoplasmosis treated respectively, with glucocorticoids, glucocorticoids and antifungals, and antifungals alone. Dogs were included in the study if they had serum antibodies against *H. capsulatum* and thoracic radiographic and bronchoscopic indications of airway obstruction. They were excluded from the study if evidence of active histoplasmosis (organisms recovered on cytologic or biopsy specimens) or other current disease was detected. None of the dogs treated with glucocorticoids had a worsening or dissemination of their disease as a result of glucocorticoid treatment. Prednisone was used at a dosage range of 2 mg/kg orally, given every 24 hours, to 2 mg/kg orally, given every 12 hours. Treatment was continued for a mean of 6.5 weeks, with a gradually tapering dosage. Glucocorticoids are not generally recommended in the treatment of active

Infectious Diseases of the Dog and Cat, 3rd Edition

histoplasmosis in people or animals because they may induce immunosuppression and dissemination of infection.

60.7.3 Immunostimulants

Interferon (IFN)- γ has been administered alone and in combination with a suboptimal regimen of AMB in the treatment of experimental disseminated histoplasmosis in mice.⁸ IFN- γ alone given subcutaneously postinfection prolonged survival over untreated controls, and combined regimens of AMB and IFN- γ reduced the fungal burden in organs as compared with either drug alone. For further information on IFN- γ see Drug Formulary, [Appendix 8](#).

60.8 PREVENTION

Effective immunoprophylaxis is not clinically available for histoplasmosis. In laboratory experiments, several constituents extracted from the cell wall and cell membrane of *H. capsulatum* protect mice against infection.¹⁶ A genetic recombinant-produced version of one of these extracts, heat shock protein 60, protects mice against challenge with yeast cells.¹⁹ Prevention consists of avoiding exposure to *Histoplasma*-infected soil in endemic areas. Soil containing bird or bat excrement enhances the growth of *Histoplasma* and is particularly dangerous. People or animals disturbing the soil, or in areas of poor ventilation such as caves, are at greatest risk. Formalin (3%) or formaldehyde solution may be used for soil decontamination if small, focal sources of infection can be identified.

60.9 PUBLIC HEALTH CONSIDERATIONS

Both companion animals and people residing in or traveling through endemic regions of the country are at risk of exposure to *H. capsulatum*. Concurrent common-source infection of people and animals has been observed; however, as with the other systemic mycoses, direct transmission of histoplasmosis from animal to animal or animal to people has not been reported.^{15,49} Fungal cultures containing mycelial growth of *H. capsulatum* are highly infectious and should be handled with extreme caution. Infections in people have occurred after kidneys, taken from donors in endemic regions, have been transplanted into patients outside endemic areas.³² Such risks might also occur in animals if such procedures become more widely used.

61 CHAPTER 61 Cryptococcosis

Richard Malik

Mark Krockenberger

Carolyn R. O'Brien

Patricia Martin

Denise Wigney

Linda Medleau

61.1 ETIOLOGY

Cryptococcosis is an important disease in people and animals and the most common systemic mycosis of cats.⁴¹ The infection is thought to be acquired from the environment, and no cases of disease transmission from one affected animal to another have been reported.^{19,40} Thus cryptococcosis is not a contagious or anthroponozoonotic disease. Occasional outbreaks of infection in people and animals, such as in British Columbia, Canada, may be the result of a common environmental source.^{57,92}

Cryptococcosis is most commonly caused by two encapsulated yeast species of the genus *Cryptococcus*—*Cryptococcus neoformans* and *Cryptococcus gattii* (formerly *C. neoformans* var. *gattii*, also *Cryptococcus bacillisporus*), although other species (such as *Cryptococcus laurenti* and *Cryptococcus albidus*) very rarely cause disease in people and animals.⁵¹ *Cryptococcus magnus* was isolated from the external ear canal of a cat with otitis externa.^{43a} The ability of *C. neoformans* and *C. gattii* to grow at 37° C may be a factor in their pathogenicity, because other members of the genus grow poorly at this temperature. Elaboration of a polysaccharide capsule and the enzymes laccase and phospholipase by *C. neoformans* and *C. gattii* are additional virulence factors that contribute to pathogenicity of these species.¹⁵

C. neoformans and *C. gattii* are dimorphic, basidiomycetous fungi.⁵⁰ They exist in animal tissues as the yeast form (*Cryptococcus* species) but are capable of transforming under special laboratory conditions into a filamentous form (*Filobasidiella* species). Unlike other dimorphic fungi, the yeast phase of *Cryptococcus* is found under routine laboratory conditions and in infected tissues. Thus far, the filamentous phase has been demonstrated only under strictly controlled laboratory conditions, but this perfect state is likely to exist in certain natural environments. The importance of the *perfect state* is that spores resulting from sexual or asexual filamentous reproduction could well represent the infectious propagules that give rise to mammalian disease.^{21,93} An unusual temperature-sensitive isolate of *C. neoformans*, which would not grow at 37° C, produced hyphal elements in a granuloma within the nasal passage of a cat and in culture at 35° C.⁶

In animal tissues, *C. neoformans* and *C. gattii* exist as a round to oval yeast with a variably sized polysaccharide capsule as its distinguishing feature. The capsule provides protection from environmental insults (e.g., desiccation) and the phagocytic response of the host. In tissues, *Cryptococcus* reproduces by forming one or two daughter cells (buds) that are connected to the parent cell by a narrow isthmus. Buds may break off when small, and thus the cell population varies in size.⁴¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Cryptococcus has a worldwide distribution and in addition to people infects various domestic and native mammals, including cats,⁶⁹ dogs,⁶² ferrets,⁶⁰ horses, goats, sheep, cattle, dolphins, birds,⁶⁴ and koalas⁴⁷ and other marsupials. In contrast to the other systemic mycoses, the prevalence of cryptococcosis in cats exceeds that in dogs. Historically, five serotypes (A, B, C, D, AD) were recognized on the basis of antigenic differences in capsular polysaccharide. Recent advances in the taxonomy of the genus *Cryptococcus* have led to a new nomenclature that was proposed at the Fifth International Conference on *Cryptococcus* and Cryptococcosis and is now generally accepted with the modification to elevate *C. neoformans* var *gattii* to species status (Table 61-1).⁵¹ *C. neoformans* and *C. gattii* differ biochemically, genetically, ecologically, and epidemiologically. *C. neoformans* has a worldwide distribution, whereas *C. gattii* is largely restricted to tropical and subtropical climates.²² *C. neoformans* can be divided into two varieties based on serotyping, *C. neoformans* var. *grubii* and *C. neoformans* var. *neoformans*. Both varieties are strongly associated with disease in human patients who are immunocompromised, although the same may not be true for companion animals. *C. neoformans* var. *grubii* is by far the most common isolate worldwide from people and animals with cryptococcosis, although *C. gattii* is important in certain geographic regions such as Australia, Papua New Guinea, Southeast Asia, and Central Africa. Strong evidence suggests that several species of Australian eucalyptus trees provide a natural environmental niche for *C. gattii*.^{22,49} Interestingly, koalas (*Phascolarctos cinereus*) serve as a sentinel host for infection and at the same time, they seem capable of amplifying the number of cryptococci in certain environments.⁴⁹ The definitive environmental niche for *C. neoformans* has not been determined, although a strong historical association exists between weathered bird (especially pigeon) guano⁴¹ and growth in decaying plant matter in hollows of certain trees.⁵⁶ *C. gattii* (serotype B) in Australia exists in highest concentration within the dead plant material in eucalyptus tree hollows (e.g., *Eucalyptus camaldulensis* and *Eucalyptus teriticornis*). In British Columbia, Canada, the organism is consistently found on living tree bark (Garry oak, maple, cedar, and pine) and air.^{4,57} *C. neoformans* passes through the gut of pigeons, but systemic infection of pigeons is extremely rare. Perhaps the pigeon's high body temperature protects it from infection.⁶⁴ Pigeon guano provide an alkaline, hyperosmolar environment that is rich in many nitrogen-containing compounds including creatinine that favor cryptococcal growth. Cryptococci may remain viable for at least 2 years in environments such as pigeon lofts, where accumulations of pigeon guano are protected from drying or sunlight.

585

Table 61-1 Major Causative Agents of Cryptococcosis

YEAST FORM (<i>CRYPTOCOCCUS</i> SPP.)		FILAMENTOUS FORM (<i>FILOBASIDIELLA</i> SPP.)	ENVIRONMENTAL NICHE	GEOGRAPHIC DISTRIBUTION

Infectious Diseases of the Dog and Cat, 3rd Edition

Most basidiomycetes reproduce sexually in their natural environment, and the teleomorphs of *C. neoformans* (*Filobasidiella neoformans*) and *C. gattii* (*Filobasidiella bacillisporus*) can be induced to undergo sexual reproduction in the laboratory and produce dikaryotic hyphae, blastoconidia, basidia, and basidiospores. The recent documentation of α - and α -mating types of *C. gattii* in *E. camaldulensis* trees suggests that this may occur in nature.³² However, recent work has suggested that *C. neoformans* may be evolving into an asexual fungus,²⁶ and basidiospores may result from haploid (monokaryotic) fruiting as well as by sexual recombination.¹⁰² In either case, the notion that the basidiospore is the infectious propagule for *Cryptococcus* is attractive, as this stage is suited to dispersal by air currents and has physical properties that favor penetration into the respiratory system, thereby facilitating primary infection of mammalian hosts.^{21,93}

Cryptococcus has various virulence factors, including its capsule, melanin, mannitol, laccase, and other enzymes. After it infects a host, the capsule thickens considerably. The capsule is a key virulence factor and is composed of glucuronoxylomannan (GXM). Two capsular genes—CAP59 and CAP64—have been associated with virulence. Capsule is continuously shed into the host's cerebrospinal fluid (CSF) and blood, where it circulates for an extended period. Capsules of the A and D serotypes are chemotactic for neutrophils. Complement fixation also results in attraction of leukocytes. The capsule may help protect the organism because it blocks the Fc portion of bound antibodies from interacting with the receptors on host phagocytes. Furthermore, encapsulated organisms do not stimulate proinflammatory cytokines and are not phagocytized or killed by phagocytes to the same degree as unencapsulated mutants. Phenotypic switching, characterized by stable alterations in cell membrane sterol composition and GXM structure, has been identified in *C. neoformans* and allows them to persist in the host by minimizing the inflammatory response.

61.2 PATHOGENESIS

The exact mode of infection is unproven, but the most likely route is via inhalation of air-borne organisms, such as basidiospores or yeast cells desiccated by environmental exposure. Shrunken, poorly capsulated cryptococci that are small enough for alveolar deposition have been isolated from pigeon guano and soil. Although human patients with cryptococcosis usually show neurologic signs referable to meningoencephalitis, strong circumstantial evidence suggests that the disease starts in the lungs and subsequently spreads hematogenously via macrophages to the nervous system. People have been shown to be colonized with *C. neoformans* var. *grubii* long before they are clinically ill.²⁷ Respiratory involvement usually does not result in human illness, although lesions can be detected in thoracic radiographs, thoracic computed tomography scans, or at necropsy. The small particle size of infectious propagules is said to be the reason the lung is primary site of infection, because only very small particles are capable of penetrating deep into the lower respiratory tract.⁴⁰ Primary cutaneous cryptococcosis is a rarely described phenomenon that occurs in people; a solitary skin lesion in unclothed areas is most common.⁸² *C. neoformans* can be found on the skin of healthy people without infection. Participation in outdoor activities or exposure to bird droppings are risk factors. Clinically healthy people are susceptible to this form of infection and a feline case was reported presumably as a result of a contaminated cat scratch injury.^{68a}

585

586

Unlike in people, in cats, dogs, koalas, and psittacine birds, the nasal cavity is usually the primary site of infection.^{47,62,64,69} The reasons for this difference are a matter of conjecture, but the more developed nasal passages in animals, which more efficiently filter small particles, may provide part of the explanation. It appears that most cases of canine and feline cryptococcosis begin as mycotic rhinitis after asymptomatic colonization of the nasal cavity. *C. neoformans* var. *grubii* has been shown to be a transient colonizer of the nasal mucus of cats, dogs, and koalas in Australia,^{47,70} whereas *C. gattii* can be isolated in sufficient numbers and with sufficient

Infectious Diseases of the Dog and Cat, 3rd Edition

frequency to be actually considered part of sinonasal normal flora of koalas in certain environments.⁴⁷ Studies in koalas have shown that self-limiting, subclinical infection is common, with limited invasion, granuloma formation, and successful eradication or containment of organisms.⁴⁷

When disease ensues, clinical signs of rostral nasal cavity disease such as sneezing, epistaxis, and nasal discharge are conspicuous, and granulomatous protuberances occasionally can be seen at the nares. In some cases, destruction of adjacent facial bones facilitates spread of infection to contiguous regions, such as the bridge and side of the nose, the planum nasale, or hard palate.⁶⁹ When facial distortion develops, the clinical symptoms strongly suggest either fungal rhinosinusitis or nasal neoplasia. In contrast, when infection begins in the caudal portion of the nasal cavity, signs of mycotic rhinitis may be subtle or absent. In other cases, caudal nasal cavity involvement gives rise to a mass lesion, which occludes one or both choanae, resulting in nasopharyngeal signs (e.g., stertor, snoring, dyspnea, open-mouth breathing).^{39,65} Occasionally the infection spreads to the middle ear via the auditory tube.⁵ It is possible to confirm the sinonasal region as the primary site of infection using cytology, culture, endoscopy, or cross-sectional imaging.

Cryptococcal infection tends to localize in the cooler areas of the body such as the respiratory passages and the subcutaneous tissue. Further spread, when evident, typically involves the central nervous system (CNS). Although the exact means of the organisms' spread into the CNS is uncertain, infection in some cases appears to extend through the cribriform plate into the olfactory bulbs and olfactory tract, giving rise to meningoencephalitis. In these cases the anatomic proximity of the optic nerves frequently results in concurrent cryptococcal optic neuritis and secondary retinitis. Clinically, symptoms include widely dilated pupils that respond poorly to light, swelling of the optic disc, and focal retinal hemorrhage. The infection typically spreads caudally within the meninges along the floor of the cranial vault. As a result, multiple cranial nerve abnormalities can develop subsequently, especially in dogs. Infection may also spread via the CSF pathways to other surfaces of the CNS, such as the dorsal aspects of the brain, and out the foramen magnum along the spinal cord. Hematogenous spread of organisms to the CNS is also possible. Cryptococcal antigen has been persistently identified in the CSF within days following experimental parenteral (subcutaneous [SC] or intravenous [IV]) inoculation of cats with *C. neoformans*.⁷⁴ Whether this represents viable organisms remains to be determined.

Multifocal cutaneous involvement in cats and dogs reflects hematogenous dissemination from the primary site of infection, as do lesions in bone (e.g., digits) or periarticular soft tissues. In ferrets⁶⁰ and the occasional cat, localized cutaneous cryptococcosis can develop after a penetrating skin injury. In some cats, infection spreads to the mandibular lymph nodes, presumably via the lymphatics from the nasal cavity. Rarely, mandibular lymphadenomegaly can be massive and require surgical debridement. Occasionally salivary gland infection has been documented, although the way the organisms reach this site is a mystery. In cattle, cryptococci from the environment enter the mammary gland via the teat canal and cause granulomatous mastitis. Primary gastrointestinal (GI) cryptococcosis can occur in very rare circumstances, with involvement of segments of bowel, mesenteric lymph nodes, stomach, and other intraabdominal structures.^{60,63}

Cryptococcosis can occur in healthy or immunodeficient individuals, although those with T-cell deficiencies are most commonly infected. In Australia, about half of infected human patients have no detectable T-cell defects. In the remaining 50%, some deficit in cellular immunity exists caused by conditions or treatments such as malignancy, chemotherapy, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), immunosuppressive drug therapy, diabetes, or sarcoidosis.⁹¹ In metropolitan communities, about 10% of patients with HIV/AIDS are likely to develop cryptococcosis in the absence of highly effective antiretroviral therapy.¹⁷ Interestingly, whereas cryptococcosis patients with HIV/AIDS invariably become infected by *C. neoformans*, *C.*

Infectious Diseases of the Dog and Cat, 3rd Edition

gattii infections tend to develop almost exclusively in healthy hosts (i.e., who do not have HIV/AIDS).^{80,91} In people with cell-mediated immunodeficiencies, severe meningitis and disseminated infections are common. After experimental inoculation of mice, the magnitude of fungemia has been correlated with the degree of brain infection.¹⁶

In eastern Australia, about 20% to 30% of human cryptococcosis cases are caused by *C. gattii*,^{80,91} with similar percentages in cats and dogs.^{62,69} Animals in rural environments tend to be infected with *C. gattii*, presumably because of increased exposure to eucalyptus material, and all cases recorded in koalas have been attributable to *C. gattii*. The development of granulomatous intracranial or pulmonary mass lesions (cryptococcomas) is strongly associated with immunocompetence. Thus in human patients, cryptococcomas are more typical of *C. gattii* infections,^{80,91} whereas *C. neoformans* infections in patients who are immunodeficient typically result in meningitis with little involvement of the brain parenchyma.

Infections with feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) have been thought to predispose cats to cryptococcosis. In North America, evidence suggests that some FeLV-positive cats develop cryptococcosis as a result of immune dysfunction because they respond more slowly or fail to respond to treatment and are much more likely to have relapses.⁴¹ In Australia, FeLV-positive cats with cryptococcosis are exceedingly rare, probably because of the very low prevalence of persistent FeLV infection in the cat population.⁶⁹ Although several reports have been made of one or two cats with cryptococcosis allegedly caused by FIV infection, studies in Australia involving large numbers of cats have failed to produce convincing evidence that cryptococcosis is a feline, AIDS-defining disease.^{69,100} Rather, it is thought that coinfection usually reflects the high prevalence of FIV infection in Australia. Leukocyte and lymphocyte subset numbers in FIV-positive and FIV-negative cats with cryptococcosis were the same, and a positive FIV status did not mean the cat had an unfavorable prognosis.¹⁰⁰ Indeed, many FIV-positive cats with cryptococcosis are cured of the fungal infection and do not relapse, despite cessation of therapy. Cryptococcosis is rarely reported in cats receiving immunosuppressive therapy or chemotherapy for malignancy.⁴³ Thus underlying diseases are typically not detected in cats with cryptococcosis, and factors predisposing to disease remain elusive. Two FIV-negative cats with cryptococcosis were treated and subsequently developed malignant lymphoma. Although no relationship was established between the two conditions, a similar association has been the subject of previous reports.^{38,59,103} In addition, two FIV-positive cats with cryptococcosis developed lymphoma and mast cell neoplasia, respectively, subsequent to developing other opportunistic infections.³ Long-standing FIV infection may have predisposed the animals to cryptococcosis and the terminal malignancies. Genetic factors may be involved in the predisposition toward development of cryptococcosis; Siamese (Fig. 61-1), Birman, and ragdoll cats and German shepherd and American cocker spaniel dogs are affected significantly more than other breeds in reported cases.^{41,69} In dogs, immunosuppressive diseases such as ehrlichiosis have been associated with cryptococcosis, but in one study, immunosuppressive factors were identified in fewer than 6% of affected dogs.⁷

Fig 61-1 Siamese cat with long-standing, invasive *C. neoformans* infection of nasal cavity. Infection has penetrated bones overlying nasal cavity, and cat's nasal bridge and forehead are swollen markedly. At surgery, this subcutaneous swelling was shown to consist almost exclusively of cryptococcal organisms rather than host tissue. (Courtesy R. Malik, University of Sydney, Sydney, Australia.)

61.3 CLINICAL FINDINGS

61.3.1 Cats

Cryptococcosis is the most common of the systemic mycoses of cats.^{23,28,40,42} No gender predisposition exists, and the age range of affected cats is broad,⁶⁹ although young adult cats (2 to 3 years old) appear to be at increased risk. It is likely that exposure and self-limiting infection occur in the first few years of life, with disease in older cats reflecting reactivation of viable cryptococci in residual granulomatous foci. Upper respiratory tract signs are most common and include sneezing; snuffling; and mucopurulent, serous, or hemorrhagic nasal discharge that is unilateral or bilateral. Signs are usually chronic and in some cases, a polyplike mass is evident in the nostril (Fig. 61-2). In others, a firm to fluctuant subcutaneous swelling over the bridge of the nose is present (see Figs. 61-1 and 61-2). Cats with nasopharyngeal cryptococcosis develop stertor, inspiratory dyspnea, a tendency to use open-mouth breathing, and occasionally, secondary otitis media.^{46,65} Often, mandibular lymphadenomegaly is evident, and ulcerated or proliferative lesions in the oral cavity occasionally develop. Lower respiratory tract signs are rare in cats. Thoracic radiographs are usually normal, although small nodular lesions may be present. Rarely, large pulmonary nodules, a mediastinal granuloma, or cryptococcal pleurisy are found.⁴¹

Neurologic signs associated with cryptococcal infection in cats vary depending on the location of lesions in and around the CNS. Common signs include depression, changes in temperament and bizarre behavior, seizures, circling, head pressing, ataxia, paresis, head tilt and other vestibular signs, anosmia, and blindness. These signs

Infectious Diseases of the Dog and Cat, 3rd Edition

may develop individually or in association with other physical findings and may result from the presence of masslike cryptococcomas or meningoencephalomyelitis. In people, cerebral cryptococcosis is often associated with increased intracranial pressure,⁸⁰ and the same is likely in cats and dogs.

Fig 61-2 A, Domestic shorthaired cat with invasive cryptococcal rhinitis that has extended to involve subcutaneous tissues on side of cat's nose. The cat was treated successfully using surgical debridement of lesion and a long course of fluconazole. B, Cytology shows capsulate yeasts, with narrow-neck budding in a DiffQuik-stained smear. (Courtesy R. Malik, University of Sydney, Sydney, Australia.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Ocular abnormalities develop in some affected cats and almost always are a marker for CNS involvement. The most common sign is peripheral blindness with dilated, unresponsive pupils (Figs. 61-3, *A* and *C*) because of optic neuritis, exudative retinal detachment, and granulomatous chorioretinitis (see Figs. 61-3, *B* and *D*; see cryptococcosis section in Chapter 93).

Cutaneous lesions are common in cats with cryptococcosis, principally from secondary involvement of the planum nasale (see Fig. 61-2, *A*). Although very rare, localized cutaneous cryptococcosis can develop after inoculation of propagules (e.g., after a cat scratch; Fig. 61-4). Multifocal skin lesions are the result of hematogenous dissemination and consist of papules and nodules that are fluctuant to firm and range from 1 to 25 mm in diameter. Larger lesions tend to ulcerate, leaving a raw surface with a serous exudate (Fig. 61-5).

587

(**A**, **B**, and **C**, Courtesy Nancy Bombaderi and Tony Reid, Adelaide, Australia; **D**, courtesy R. Malik, University of Sydney, Sydney, Australia.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Cats with disseminated disease also may have enlargement of one or more lymph nodes, with cryptococci evident in aspirates from affected nodes. Fever is uncommon in affected cats. Cryptococcosis is typically a chronic infection, causing listlessness and weight loss due to poor appetite. Other reported signs include change in personality or behavior, peripheral lymphadenomegaly (unassociated with skin lesions), bone lysis, swollen digits, chronic cough, and renal failure due to kidney involvement.⁴¹

61.3.2 Dogs

Cryptococcosis is a disease that develops predominantly in young adult dogs, and most dogs are younger than 4 years old at diagnosis.⁶² No gender predisposition exists. Doberman pinschers, German shepherd dogs, and American cocker spaniels are affected more than other breeds.^{41,62} German shepherd dogs susceptible to cryptococcosis presumably have the same genetic predisposition that is responsible for their susceptibility to other systemic fungal infections such as disseminated aspergillosis.

Weight loss and lethargy are common nonspecific findings. Major organ systems affected by canine cryptococcosis include the nasal cavity, CNS, and the eyes. CNS signs are typically multifocal, caused by meningitis and progressive meningoencephalomyelitis, and include head tilt; nystagmus; facial paralysis; paresis, paraplegia, or tetraplegia (usually the upper motor neuron type); ataxia; circling; seizures; and cervical hyperesthesia.^{7,8} The most common ocular abnormalities consist of optic neuritis, exudative granulomatous chorioretinitis, and retinal hemorrhage associated with dilated pupils and blindness. Occasionally, anterior uveitis develops, as does periorbital swelling. Rhinosinusitis from cryptococcosis may be subclinical, thus its incidence may be underestimated because respiratory signs are frequently not reported in dogs that show florid neurologic signs.^{22,62}

588

589

Fig 61-4 Localized cutaneous cryptococcosis in Siamese cat. It was suspected that this lesion resulted from inoculation with numerous infectious propagules of *C. neoformans* after a cat-scratch injury. The cat had no concurrent nasal signs and responded rapidly to short course of fluconazole. (Courtesy R. Malik, University of Sydney, Sydney, Australia.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Cutaneous involvement, as in the cat, is a marker for disseminated disease. Skin lesions consist of papules, nodules, or ulcers that may involve any portion of the integument, the nose, tongue, gums, hard palate, lips, or nail beds. Some dogs develop fever. Less common clinical signs include lameness caused by lytic bone lesions and peripheral lymphadenomegaly. [Table 61-2](#) summarizes medical problems associated with cryptococcosis in dogs and cats.

61.4 DIAGNOSIS

61.4.1 Specimen Collection

In most of the previously mentioned conditions, definitive diagnosis is straightforward and based on obtaining representative tissue specimens for cytology, culture, and occasionally histology.¹⁹ Suitable specimens may include deep nasal swabs, nasal washings, needle aspirates from cutaneous nodules or enlarged lymph nodes, bronchoalveolar lavage specimens, pleural fluid, and CSF. A definitive diagnosis of cryptococcosis can be made by culture and identification of the organism by a reputable laboratory. However, it is possible to obtain a high index of suspicion of cryptococcosis by identifying characteristic capsulate, narrow-necked budding yeasts in cytologic smears or histology sections.

61.4.2 Cytologic Examination

Romanowsky-type stains (DiffQuik, Giemsa, and Wright), new methylene blue, and Gram stain are all satisfactory for making a cytologic diagnosis. DiffQuik is simple and reliable ([Fig. 61-6, A](#)). With Gram stain the organism retains the crystal violet, whereas the capsule stains lightly pink with safranin. The organism is often most easily visualized at low power ($\times 10$). India ink has been used historically to examine CSF for cryptococci, which appear unstained and silhouetted against a black background (see [Fig. 61-6, B](#)). In the authors' experience, India ink is not as helpful as other stains because lymphocytes and fat droplets are easily confused with the organism. More success demonstrating yeasts in CSF has been achieved using cytocentrifuged preparations stained with DiffQuik and then culture, than with India ink preparations. Cytologic examination can also be performed on crush preparations of biopsy samples.

Cytologic examination of nasal or cutaneous exudates, masses, CSF, or ocular fluid demonstrate organisms in a majority of cases, although culture can be a more sensitive test. Urine sediment should be evaluated because many dogs and some cats have subclinical renal infection.⁴¹ In human patients, blood culture is often useful; however, it has not been well evaluated in dogs or cats. Although cytologic examination is a rapid test, negative test results do not eliminate the possibility of cryptococcosis. Poorly capsulated organisms may be overlooked unless large numbers are present; if a sufficient index of suspicion exists, additional diagnostic tests are indicated. Generally, cryptococcal organisms are only found by cytologic examination of CSF in only 40% to 70% of humans and 60% of veterinary patients.²⁴

61.4.3 Serologic Testing

The detection of cryptococcal capsular antigen by the latex agglutination procedure is the most widely used serologic test and is very useful in a veterinary setting.^{66,76} Various detection methodologies exist.¹⁹ The test used in the authors' laboratory detects polysaccharide antigen using latex particles coated with anticryptococcal antibodies. Tests detect all known serotypes and can be used for serum or CSF. They provide a rapid diagnosis when organisms have not been visualized or cultured (Table 61-3). In human studies, commercial kits typically demonstrate 90% to 100% sensitivity and 97% to 100% specificity.^{81,95} Results have been similar for animals.^{47,60,64,66} The sensitivity and specificity of polysaccharide antigen test has been improved by pretreatment of test specimens with pronase (a proteinase).³¹ This digestion step is included with some test kits but should be performed routinely, even when the enzyme is not supplied by the manufacturer.^{19,66}

Testing for cryptococcal antigen in serum may prove advantageous when CSF collection is unacceptably risky or a diagnosis of cryptococcosis is unlikely but should be excluded. For example, all cats and dogs with intracranial signs should be tested for cryptococcal antigen before CSF collection or brain imaging. Numerous canine and feline patients have experienced a marked deterioration in neurologic status after CSF collection, despite the use of appropriate anesthetic regimens. This is hardly surprising, considering that many animals have intracranial mass lesions or increased CSF pressure—with the additional risk of brain herniation following a cisternal tap. If cryptococcal meningitis is suspected, only limited amounts of CSF should be removed to reduce the risk of brain shifts during the procedure.

Infectious Diseases of the Dog and Cat, 3rd Edition

Antigen titers can be extremely high (>1:65,536) in cats and dogs with disseminated disease, but even a titer of 1:2 is considered a positive result.⁶⁶ Titer results from different kits can vary considerably, thus the methodology should not be altered when monitoring the response to treatment. When monitored consistently, titers have proven useful in evaluating patients' progress during therapy. A good prognosis is indicated by a decrease in antigen titer, whereas a persistent titer after treatment suggests continued infection. Reductions in the titer typically lag behind clinical improvement. No correlation has been found between pretreatment antigen titer and outcome.

In human patients, measurement of the antigen titer in CSF is often more sensitive than cytology or culture and therefore is theoretically preferable to serum in animals with neurologic signs. However, the authors' experience is that most patients with CNS cryptococcosis have positive antigen titers in serum, presumably because sufficient antigen is released from the primary site of infection. Cryptococcal antigen can also be detected in other body fluids such as pleural fluid or bronchoalveolar lavage fluid.

Although cats, dogs, and koalas all make anticapsular antibodies in response to infection, subclinical disease with seroconversion is common. Because titer cutoffs have not been determined with certainty, antibody determinations are currently a research tool rather than a clinical tool.^{23,68}

61.4.4 Tissue Biopsy

Because of the rapidity of cytologic evaluation, impression smears or potassium hydroxide (KOH) preparations should always be made from suspect biopsy samples. If no organisms are seen, part of the sample can be used for culture, and the rest can be processed for routine histology. In sections stained with hematoxylin-eosin (H and E) stain, the organism appears as a faint, eosinophilic, round to oval body surrounded by a clear halo (the unstained capsule). The organism is more easily visualized with periodic acid-Schiff, methenamine silver, or Fontana-Masson stain, although the capsule still does not stain well with these methods. Mayer's mucicarmine is the definitive stain; the cryptococcal capsule takes on a rose-red color, and the organism appears pink against a blue background. Other fungi with similar morphologic features do not stain with this method. The large capsule and the thin cell wall of *Cryptococcus* species differentiate them from *Blastomyces* organisms. The budding and lack of endospores of cryptococcal organisms distinguish them from *Coccidioides* species. However, some *C. neoformans* strains have poorly developed capsules. When unsure about the presence of cryptococci and only formalin-fixed tissues are available, immunohistology can be used to differentiate the organisms from other fungi and identify their species and serotype.⁴⁸ This technique is also very useful for examination of archived material.

61.4.5 Genetic Identification

The polymerase chain reaction (PCR) could be used as a highly sensitive and specific means of identifying cryptococcal infection if other means fail. However, it is not regarded as a routinely useful clinical tool. Detection of the CAP59 gene was used to detect *C. neoformans* in a cat,⁴³ and a nested PCR was developed to detect *C. neoformans* in CSF.⁸⁸ The CAP59 gene was also detected in urine, serum, and biopsy samples of two cats with cryptococcosis.⁸⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

61.4.6 Mycology

The organism can be easily cultured from aspirates, exudate, CSF, urine, and tissue specimens. Although *C. neoformans* and *C. gattii* grow on almost all laboratory media, Sabouraud's dextrose agar is preferred when fungi are being considered in the differential diagnosis. Standard Sabouraud's agar, without antibacterial additives, is optimal when culturing a normally sterile site such as CSF, because antibiotics included in the media may inhibit the growth of some cryptococcal strains.¹⁹ During sampling of a site normally contaminated by bacteria (e.g., the nasal cavity), inclusion of antibiotics in the medium improves the chances for isolating cryptococci. Growth of *Cryptococcus* species is inhibited by media containing cycloheximide. Culture should be performed at 25° C and 37° C. Colonies become visible within 2 to 10 days, but typically in 2 to 3 days. The organisms form white, creamy colonies that yellow with age, are mucoid if the strains are heavily capsulated, and are dry if the capsules are poorly developed. *C. gattii* colonies are typically much more mucoid than *C. neoformans* colonies. Characteristics used to identify the organism include its morphology (presence of a capsule, narrow-necked budding), growth at 37° C, hydrolysis of urea, brown-color effect on bird seed agar, growth and color change on canavanine glycine bromothymol blue agar,⁵² and response to the various assimilation tests that are available as commercial kits. Culture results of CSF are usually positive in patients with CNS cryptococcosis. Thus fungal culture is recommended when CSF is collected from patients with inflammatory CNS disease, even if the organism cannot be demonstrated cytologically or serologically.

Fig 61-7 *C. neoformans* (left) and *C. albicans* (right) plated onto Staib's birdseed agar. Note prominent brown-color effect of *C. neoformans* colonies. (Courtesy R. Malik, University of Sydney, Sydney, Australia.)

Birdseed agar that contains antibiotics can be useful in the diagnosis of cryptococcosis, especially with sampling sites expected to be heavily contaminated with bacteria, such as nasal exudate.⁴⁹ It is also an ideal media for environmental studies. Normally, bacteria and other fungi outgrow *C. neoformans* and *C. gattii* on plates; birdseed agar containing antibiotics suppresses growth of contaminants while distinguishing colonies of *Cryptococcus* species from other yeasts and filamentous fungi by the brown-color effect produced in the agar (Fig. 61-7).

Fungal susceptibility testing using disk diffusion, Etest strips (e.g., AB Biodisk, Solna, Sweden), or broth microdilution provides useful information concerning therapy. Although not as accurate as bacterial in vitro susceptibility testing, the strains that have a low minimum inhibitory concentration for a given drug in vitro tend to be susceptible to the drug in vivo, although the converse is not always true.

Infectious Diseases of the Dog and Cat, 3rd Edition

61.5 PATHOLOGIC FINDINGS

A lesion associated with cryptococcosis can vary from being a gelatinous mass consisting almost exclusively of organisms to being a well-ordered, cell-mediated immune (CMI) response resulting in granuloma formation. The gelatinous appearance is a reflection of the large amount of capsular polysaccharide present in lesions. The primary cellular response comprises neutrophils, macrophages and giant cells, with a few plasma cells and lymphocytes. Generally, the presence of a granulomatous response is indicative of an immunocompetent host. A weak or absent response suggests either overwhelming disease or immunodeficiency (although the center of large lesions, even in immunocompetent hosts, often has a limited response to organisms).

591

592

Fig 61-8 Necropsy photograph of cross-section of nasal cavity of Burmese cat with granulomatous cryptococcal rhinitis. The cat developed FIP during therapy and was euthanized. Note diffuse thickening of turbinates. (Courtesy R. Malik, University of Sydney, Sydney, Australia.)

61.5.1 Cats

In cats that die or are euthanized, granulomatous rhinitis is usually evident (Fig. 61-8), and in rare instances the lungs are affected also. Cerebral cryptococcosis consists of either primary meningoencephalitis⁴¹ or a cerebral granuloma (Fig. 61-9).^{25,29} Optic neuritis (see Fig. 61-3, D) is common in cats that die of cerebral cryptococcosis, and in some cats the olfactory bulbs are replaced by a gelatinous mass of yeast cells. Other affected organs include skin and subcutaneous tissues, kidneys, and lymph nodes that drain infected areas. Renal granulomas have been found in some cats with disseminated disease, as have lesions in the spleen, adrenal glands, thyroid glands, and liver.

Infectious Diseases of the Dog and Cat, 3rd Edition

61.5.2 Dogs

Dogs that die or are euthanized because of cryptococcosis infection usually have CNS infection, ocular involvement, or widely disseminated disease. The lesions consist of meningoencephalitis; neuritis of the optic, facial, or vestibular nerves; and granulomatous chorioretinitis. At least 50% of dogs in reported cases have lesions in the respiratory tract—usually the nasal cavity (Fig. 61-10), lungs, or mediastinum.

61.6 PROGNOSIS

The prognosis for many cats and dogs with cryptococcosis is good or excellent if they have diligent, cooperative owners who are prepared to medicate their pets for many months and pay for the costs of drugs and monitoring.

Animals with longstanding, extensive disease have a less favorable prognosis than patients diagnosed early with mild signs of disease, although even longstanding, severe cases can be cured. Patients with neurologic signs always have a guarded prognosis, although many (perhaps two out of three) can be treated successfully using combination therapy including amphotericin B (AMB). Two additional considerations apply to patients with cryptococcal meningoencephalitis. First, neurologic status often deteriorates soon after starting therapy, presumably because death of cryptococci and the resulting inflammation give rise to a dangerous increase in intracranial pressure.⁶³ Second, neurologic deficits such as blindness and gait abnormalities may persist, even after successful therapy.⁶²

Cats in which a persistent positive FeLV status is confirmed by testing on at least two consecutive occasions have a poor long-term outlook, so drug therapy for cryptococcosis in these animals should be considered palliative.⁷⁵ In contrast, many FIV-positive cats can be cured, although some need a prolonged course of treatment, and recurrence or the development of other clinical problems remain possible.

61.7 THERAPY

One of the reasons for renewed veterinary interest in cryptococcosis was the availability of a new generation of triazole antifungal drugs (fluconazole [FCZ], itraconazole [ITZ], and voriconazole [VCZ]) suitable for long-term oral administration and the development of new ways to use AMB more easily and safely. The main problems in treating cryptococcosis is the high cost of therapy, the multiple hospital visits, and the regular medication of pets for a protracted period.

Treatment of immunocompetent animals may be curative; immunocompromised hosts may have recurrences or persistent infection. Table 61-4 lists factors that play a role in the therapeutic approach to dogs and cats with cryptococcosis.

61.7.1 Surgical Intervention

When it is feasible, surgical excision of large aggregations of fungus-infected tissues before or shortly after starting medical therapy is a prerequisite for successful treatment. For example, cats with extensive involvement of the nasal bridge, large nasopharyngeal masses (Fig. 61-11), or massively enlarged lymph nodes benefit enormously if abnormal tissue is removed surgically early in the course of treatment.³⁹ This prevents problems with diffusion of antifungal agents into poorly perfused tissues, because they may consist almost exclusively of cryptococcal elements. In some cases the nasal masses can be dislodged by “traumatic” flushing

Infectious Diseases of the Dog and Cat, 3rd Edition

or by simultaneous massaging through the soft plate. Endoscopic visualization can be helpful during these procedures. In other animals, surgical incisions must be made through the soft palate to remove granulomas. Nasopharyngeal lymphoma can appear very similar to cryptococcal caudal nasal granulomas.

61.7.2 Therapeutic Agents

Five drugs are available for treating cryptococcosis in cats and dogs ([Table 61-5](#)). Each has a role in therapy, which varies depending on the individual animal being treated.

61.7.2.1 Amphotericin B

AMB is the most effective anticytotoxic agent. It is the only drug that is fungicidal and whose ability to permanently eradicate CNS infections has been proven. It must be given parenterally, therefore its administration requires a hospital visit. It is nephrotoxic, although the condition is at least partially reversible. The combination of AMB and flucytosine (FCY) is considered the optimal therapy for cats and dogs with severe or widely disseminated disease, especially when the CNS is involved. Newer forms of

592

AMB such as liposomal and lipid complex preparations⁴⁶ are not necessarily more effective but are less nephrotoxic, which in a veterinary setting may translate into greater efficacy, although at a substantially increased cost. Heat-pretreatment (60° C to 70° C for 10 minutes) of standard formulations of AMB immediately before administration (see Drug Formulary, [Appendix 8](#)) substantially reduces nephrotoxicity, thereby increasing the dose that can be given safely.^{54,55,87} Because AMB is an established drug that has been used for quite some time, it is relatively inexpensive, apart from the costs associated with the administration IV or as an SC infusion.⁶¹

Infectious Diseases of the Dog and Cat, 3rd Edition

61.7.2.2 Flucytosine

FCY is a useful, effective, and moderately expensive drug. Because of the rapid resistance that can develop when it is used alone, it is used chiefly to improve the efficacy of other antifungal drugs.³⁷ It shows true synergy when combined with AMB and is particularly good at penetrating the CSF and blood-brain barriers.⁶¹ Thus combination therapy using AMB and FCY is the ideal initial treatment for cryptococcosis in human patients, and the authors believe the same is true for canine and feline patients. Relapses in people are lower when FCY is combined with another drug during the first 2 weeks of therapy.⁸⁹ Unfortunately, dogs receiving FCY almost invariably develop a severe drug reaction, typically 10 to 14 days after starting therapy.⁶⁷ This reaction is so severe that it precludes additional FCY therapy and causes a temporary setback in the patient's clinical course. FCY has also been given together with azoles to improve their efficacy.^{61,78}

61.7.2.3 Fluconazole

Undoubtedly, FCZ may be the most desirable and effective drug for treating cryptococcosis and is certainly more effective than ketoconazole (KTZ) for the majority of isolates, with its good penetration of the brain, eye, and urinary tract and its minimal side effects. It is water soluble and excreted by the kidney, reaching high concentrations in urine. Cryptococcus is not usually a urinary pathogen, so this is not a deciding factor for FCZ's use. It has been recommended for treating CNS infections because of its penetration of the CNS^{44,89}; however, its efficacy in this treatment has not yet been substantiated (see Management of CNS Infections in this chapter). However, FCZ is so expensive that only very wealthy or dedicated owners can afford it, particularly for long courses of therapy. In situations involving no financial limitations, FCZ may be a drug to consider for initial therapy.⁶⁹ Cost considerations are directly proportional to the size of the patient. When the drug is out of patent, the availability of generic preparations should reduce the current high cost of therapy.

61.7.2.4 Itraconazole

ITZ is currently the drug of choice for treatment of most cases of cryptococcosis in cats.^{42,74,75} It is more effective than KTZ, with generally fewer side effects and a higher therapeutic index, and it is given only once daily. An oral suspension containing cyclodextrin has greater bioavailability than oral capsules (see Drug Formulary, [Appendix 8](#)). Importantly, it is significantly less expensive than FCZ, with which it has comparable to slightly inferior efficacy for infections that are not in the CNS, eye, or urinary tract. Adverse effects include anorexia, vomiting, and hepatic disease associated with elevated alanine aminotransferase (ALT) activity. Rarely, vasculitis with severe cutaneous ulceration can develop. It is metabolized by the liver and extensively distributed to lipophilic tissues. Its concentration in kidney, liver, and skin is 2 to 20 times greater than in plasma. Although it is not well distributed into the CNS, ITZ still has been used to successfully treat humans, cats, and dogs with cryptococcal meningitis.^{18,40,75} Like KTZ, ITZ should be given with food to maximize its bioavailability.

594

Table 61-5 Therapy for Cryptococcosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL	DURATION (MONTHS)
Flucytosine and/or	C	30	PO	6 hr	1–9
		50	PO	8 hr	1–9
		75	PO	12 hr	1–9
	C (≥3.5 kg)	250 mg total	PO	6–8 hr	1–9

	C	10–20	PO	24 hr	6–18 ^g
	C (≤3.5 kg)	50 mg total	PO	24 hr	6–18 ^g
	C (>3.5 kg)	100 mg total	PO	24 hr	6–18 ^g
	C (≤3.5 kg)	100 mg total	PO	48 hr	6–18 ^g
Fluconazole	B	5–15	PO	12–24 hr	6–18 ^g
	C	30–50 mg total	PO	12 hr	6–18 ^g

C, Cat; D, dog; B, both dog and cat; PO, by mouth; IV, intravenously; SC, subcutaneously; ITZ, itraconazole; FCZ, fluconazole; AMB, amphotericin B.

- See [Appendix 8](#), Drug Formulary, for additional information on these drugs.
- Dose per administration at specified interval.
- Until a minimum cumulative dosage of 10 mg/kg is reached. For some dogs, cumulative dosages as high as 40 mg/kg have been given over prolonged periods of several months. For cats receiving 2 infusions per week, 0.5 to 0.8 mg/kg is given per infusion.
- Add each dose to 400 ml of 0.45% saline, 2.5% dextrose; for dogs over 20 kg, add AMB to 900 ml of 0.45% saline and 2.5% dextrose.⁶¹ See
- With lipid-complex drug, dose per administration and cumulative dosage may be slightly increased; has been effective for blastomycosis (see
- If toxicity develops, the dose should be changed to 50 mg/kg cat every other day.
- Range may vary from 6 to 10 months depending on remission of clinical signs and antigen titers.
- If lack of response to therapy or toxicity is noted at these dosages, then ITZ, FCZ, or AMB lipid preparations should be used.

61.7.2.5 Ketoconazole

KTZ is the least expensive of the available drugs, although doses that have good efficacy in vivo often result in inappetence and vomiting, especially in cats with capricious appetites. However, in some patients, it is

Infectious Diseases of the Dog and Cat, 3rd Edition

effective even when given as monotherapy. It also seems useful against *C. gattii* isolates from the Vancouver Island region.⁵⁷

61.7.3 Management Regimens

Based on these considerations, an optimal plan has been developed for dealing with cryptococcosis in small animals. First, procure material to culture the organism, determine the species and variety, and ideally, obtain in vitro susceptibility data. Second, obtain a serum sample to determine baseline biochemical measurements, FeLV and FIV status, and permit future measurement of the pretreatment cryptococcal antigen titer. A portion of the serum sample should be stored frozen, because sequential antigen titers used to monitor therapy should ideally be processed in the same assay run. Third, surgically debulk easily accessible, localized accumulations of fungus-infected tissues. This may be done at the outset or after a short period of drug therapy, depending on convenience, the physical status of the patient, and the initial response to therapy. The subsequent management of the case depends on the severity of disease and whether the CNS is involved.

61.7.3.1 Cats with Mild to Moderate Disease without CNS Involvement

Commence therapy with ITZ, 50 to 100 mg per cat once daily with food. Medium- to large-size cats should receive 100 mg once daily, whereas cats weighing 3.5 kg or less should receive 50 mg daily or 100 mg every other day.^{74,75} ITZ capsules can be opened and split into two 50-mg portions using empty gelatin capsules or with the help of a compounding pharmacist. Alternately, the content of the capsules can be mixed with small portion of a tasty food treat or butter and given at the start of the meal; the ITZ formulation has no discernable effect on texture or palatability of food. The oral suspension should also be considered to achieve appropriate dosing and better systemic absorption. Many cats eventually develop liver toxicity during therapy with ITZ, especially when given high doses. The toxicity can take several weeks to months to develop, and its clinical symptoms include reduced appetite and possibly vomiting. Invariably a concurrent elevation in serum ALT activity occurs. ITZ-induced hepatotoxicity is reversible on discontinuation of the drug, although it can take as long as 7 days for cats to regain their appetite and demeanor. Once this occurs, it is generally possible to safely administer the drug again, albeit at a reduced dose—typically 50% of the dose given originally. In a minority of animals, it is necessary to change therapy to FCZ.

595

596

Therapy should be continued until the cat appears completely healthy, with resolution of all clinical signs and eradication of viable organisms from accessible tissues (as assessed by cytology and culture). Typically, this takes 3 to 12 months, although some cats require even longer. When this stage has been reached, a second serum sample should be obtained from the cat to determine the extent of the antigen titer decrease caused by therapy. A fourfold to fivefold reduction suggests successful therapy, so when this level has been obtained, it is recommended to continue ITZ (possibly at a reduced dose) or alter therapy to KTZ (50 mg once daily with food) until the antigen titer decreases to zero. If the antigen titer has decreased but is still substantial, then ITZ therapy should be continued as before, because it is likely that a substantial amount of viable fungus remains in the cat's tissues. If the antigen titer has not decreased, then more aggressive therapy should be implemented as described in the following section.

Generally speaking, the antigen titer should drop by at least 1 dilution (twofold) per month during effective therapy; failure to observe a decrease of this order strongly suggests the need for more aggressive therapy. However, in the interests of economy, the antigen titer does not need to be determined for several months if the cat is doing well and visible lesions have been regressing.

Infectious Diseases of the Dog and Cat, 3rd Edition

FCZ can be used in the same way as ITZ, although in some locations, it is substantially more expensive. It is a very effective agent for treating cryptococcosis,⁶⁹ well tolerated even at high doses, and largely devoid of serious side effects. The authors generally use an oral dose of 30 to 50 mg per cat every 12 hours, for small and large cats, respectively. Some pharmacokinetic studies suggest lower doses achieve therapeutic blood levels,⁹⁹ but experience shows that higher doses are required in vivo to successfully treat many cats with cryptococcosis. One advantage of FCZ over ITZ is that it reaches effective concentrations in the CNS and CSF (even in the absence of inflammation) and is less likely to cause hepatic or other toxicities. Largely for financial reasons, the use of FCZ is often reserved for cats with CNS involvement or in cats that develop exaggerated toxicity during ITZ therapy. The latter subgroup of cats generally responds favorably to FCZ.

61.7.3.2 Cats with Severe Disease, with CNS Infections, or Failing to Respond Adequately to Azoles

Cats with advanced, disseminated, or severe disease and patients with CNS involvement may improve with oral azole therapy; however, these cats respond more quickly and have better outcomes if treated with AMB and FCY.⁶¹ If the animals are sufficiently debilitated to require IV fluid therapy, give the AMB as a continuous IV infusion (0.5 mg/kg/day) in 0.45% saline and 2.5% dextrose supplemented with 20 mmol of potassium chloride per liter at 4 ml/kg/hour (twice the maintenance requirements).

Otherwise, use a protocol in which AMB is administered 2 or 3 times weekly as a SC infusion.⁶¹ AMB is prepared by adding 10 ml of sterile distilled water to a 50-mg vial of Fungizone® (Bristol-Myers Squibb, Princeton, N.J.) to produce a 5 mg/ml colloidal suspension. Once prepared, the AMB suspension can be stored frozen for up to 4 weeks without a loss of efficacy. When required the stock solution is thawed, and the calculated dose is aseptically aspirated from the vial, which is subsequently refrozen. Thawing the frozen AMB in very hot tap water may reduce its nephrotoxicity, which was discussed in a previous section. To prepare an SC infusion of AMB, a 500-ml bag of 0.45% saline in 2.5% dextrose is heated to 40° C in a microwave oven and then connected to a fluid-administration set; 100 to 150 ml is discarded. The calculated dose (0.5 to 0.8 mg/kg; typically 0.4 to 0.8 ml) of the stock AMB suspension is injected into the fluid bag through its injection port. Fluid is then aspirated and injected back and forth into the syringe repeatedly to ensure effective transfer of AMB to the bag.

A 19-gauge needle is then attached to the fluid administration set and inserted into the SC space between the scapulae roughly on the midline. The fluid is allowed to flow as fast as gravity allows. Raising the bag of fluid as high as possible facilitates rapid delivery of the infusion, which usually takes approximately 10 minutes. It is preferable to deliver the entire volume (350 to 400 ml) in one site, although the needle occasionally may be repositioned caudally if the cat becomes very uncomfortable after half or more of the fluid has been administered. In general, the SC infusion is well tolerated by cats that do not resent restraint per se. In fractious cats, sedation using midazolam/ketamine or light anesthesia using sevoflurane (Abbott Laboratories, Abbott Park, Ill.) is necessary. The fluid moves extensively through the SC space, tending to pool ventrally for several hours before being absorbed.

The infusions are continued 2 to 3 times per week until obvious clinical improvement and a corresponding decrease in the antigen titer are noted. Typically the cumulative dose of AMB required is 10 to 20 mg/kg. Interestingly, it is the cumulative dose that appears to be important rather than the period over which the drug is administered. Using AMB SC as a dilute suspension delays its absorption into the systemic circulation. This type of administration prevents the high peak blood levels that cause renal damage.

Infectious Diseases of the Dog and Cat, 3rd Edition

Administering AMB together with a large volume of fluid (and sodium) also reduces the likelihood of developing nephrotoxicity, because of the protective effect of the ensuing diuresis. Therefore it is possible to administer larger and thus more effective quantities of AMB using this protocol than have been administered traditionally. It is prudent to monitor serum urea and creatinine concentrations regularly during therapy and temporarily discontinue therapy if azotemia develops. Owners are also advised to add a small amount of salt to the cat's diet, because it should also help minimize renal toxicity.

FCY is administered orally in concert with AMB at a dose of 250 mg (1/2 tablet) every 8 hours for average-sized cats and every 6 hours for large cats. This drug is generally well tolerated by cats, although the authors know of one cat that became thrombocytopenic during therapy. In some cats with neurologic signs, FCZ is administered also, although the use of azoles is often reserved for a later stage in therapy.

AMB is continued on a schedule of 2 or 3 times per week. If animals are hospitalized, treatment is given on a Monday-Wednesday-Friday schedule (0.5 mg/kg per infusion), whereas cats treated as outpatients receive two infusions per week (0.5 to 0.8 mg/kg per infusion) for the owner's convenience. After this therapy is started, it is usually continued for at least 6 to 12 weeks, at which time the patient is usually well enough to be given follow-up oral azole therapy until the antigen titer decreases to zero. In some cats, an additional course of AMB infusions is required later (e.g., if the decrease in the antigen titer is not sustained during azole therapy). If mild azotemia develops, it is necessary to discontinue combination therapy for a few weeks. This is usually more of a problem in older cats that have lost some renal reserve. Cats are given ITZ or FCZ while AMB/FCY therapy is temporarily discontinued.

Based on the authors' experience of managing numerous cases of cryptococcosis in cats, dogs, and koalas, it is certain that therapy incorporating AMB is more effective than oral therapy using either ITZ or FCZ, thus this regimen is recommended for severe or intractable cases and all cats with CNS disease. However, treatment using this combination requires much more effort and dedication from the owner and the veterinary team. Because many patients with CNS involvement deteriorate during initial treatment with AMB and FCY, short-acting glucocorticoids such as prednisolone may be necessary to support patients during a critical 1- to 2-day period of increased intracranial pressure.⁶³ Occasionally, cats develop sterile abscesses at sites of fluid administration, but they usually resolve spontaneously; in some cats, it may be more expedient to aspirate an obvious accumulation of pus. These infusion reactions appear in some cats and not others and are more likely to occur when the infusion remains localized rather than spreading extensively through the SC space. Tonicity of the solution should also be reduced to help alleviate the occurrence of this reaction (see Dogs section that follows). 596
597

Finally, it is vital to support these cats during the initial phase of therapy. This may involve IV fluid therapy, force feeding, or tube feeding. Generally, cats improve significantly within 1 to 2 weeks of starting therapy, and it is unusual for them to be hospitalized for longer than this at the outset.

61.7.3.3

Dogs

The majority of dogs with cryptococcosis have severe disease, and it is typically disseminated, has CNS involvement, or both. Furthermore, dogs affected are often the large breeds, which makes dosing with azoles (especially FCZ) too expensive for most owners. No reports have been published of CNS cryptococcosis in dogs that have been cured with FCZ alone. In one dog, surgical debridement of an extradural spinal cord granuloma combined with fluconazole treatment (an oral dose of 5.5 mg/kg daily) controlled spinal cord infection.⁴⁴ In a dog with disseminated CNS cryptococcosis, FCZ therapy (ranging from 4.2 to 9.1 mg/kg/day over 47 weeks) resulted in prolonged substantial clinical improvement for 1 year with eventual

Infectious Diseases of the Dog and Cat, 3rd Edition

progression of neurologic signs.⁹⁶ In another dog with disseminated cryptococcosis that included the CNS, continual therapy with FCZ (5 mg/kg every 12 hours) caused clinical improvement in neurologic signs during 60 weeks of monitoring; however, the recovery was incomplete, and active chorioretinitis persisted despite therapy.⁸⁶

In people, initial AMB and FCY combination therapy is preferred to FCZ for CNS infections; however, FCZ is used as a follow-up therapy on a long-term basis after remission has been achieved. The vast majority of dogs with cryptococcosis are young adults, and they are much more tolerant of AMB than cats, therefore higher individual and cumulative doses can be safely administered. In most canine patients, especially large dogs or those with meningoencephalitis, AMB therapy is the most effective and inexpensive treatment. ITZ is an important drug for treating less severe cases or maintaining treatment after an initial 2-month induction period of AMB therapy. In people and in some dogs, a dramatic worsening of signs may be seen during institution of combination therapy, presumably because of the release of organisms or fungal antigens into the CSF and resultant osmotic or inflammatory changes. Repeated removal of CSF or temporary antiinflammatory therapy may be needed to keep animals from developing complications of severe increases in intracranial pressure.

SC infusions are given to dogs in a similar way that they are given to cats—either 2 or 3 times per week—and it is even possible to train exceptional owners to give the infusions at home, because dogs are much more tolerant of the procedure than cats. When making up AMB infusions, it is important to remember that the drug is irritating, so a concentration of 20 mg/L should not be exceeded. Thus when treating dogs that weigh more than 20 kg, it is necessary to suspend the AMB in 1000 ml of 0.45% saline and 2.5% dextrose, whereas dogs weighing less than 20 kg usually require a 500-ml infusion. Despite this precaution, some dogs develop sterile abscesses at the site of fluid administration, although they usually resolve spontaneously. Occasionally, the abscesses are severe; in these individuals, AMB can be given as an IV infusion over several hours preceded by 30 to 50 ml/kg of crystalloid solution IV (over 1 hour) on a twice-weekly basis.

It is difficult to recommend routine adjuvant FCY therapy in dogs. Like many human infectious disease physicians, the authors believe that FCY enhances the efficacy of AMB. However, the drug eruption that invariably ensues is a real setback to patients.⁶⁷ Currently, we therefore recommend that if FCY is given, therapy should be closely monitored and discontinued at the first sign of malaise, fever, facial pruritus, or mucocutaneous ulceration. Almost certainly, FCY should not be continued for longer than 14 days in any patient unless a very strong clinical justification exists. Many veterinarians may feel more comfortable using combination therapy consisting of AMB and ITZ (10 mg/kg orally with food once daily) from the outset to avoid this potential complication.

Most young dogs are very tolerant of AMB, and cumulative doses as high as 40 mg/kg can be given safely over a prolonged period, although it is sometimes necessary to temporarily discontinue therapy for several weeks in the middle of a course of therapy to permit azotemia to resolve. ITZ is given during this period. The ability to safely administer a large dose of AMB results in less need of follow-up azole therapy in canine patients. Although ITZ (5 to 10 mg/kg orally once daily) should be continued until the antigen titer is zero, the authors have had many patients in which this was not possible but whose antigen titers continued to decline to zero after 2 to 3 months of AMB infusions. The antigen titer does not distinguish between the polysaccharide material elaborated by viable yeast cells and the dead organisms being phagocytized by the host.

Infectious Diseases of the Dog and Cat, 3rd Edition

61.7.3.4 Long-Term Follow-Up

One of the greatest challenges in treating animals is to ensure that the infection is eliminated from the patient permanently. Serial antigen titer determinations are most useful in this regard because patients typically improve clinically long before viable fungus is eliminated from the body. This is especially true during monotherapy with azoles, which are fungistatic and rely on a CMI response and phagocytosis to actually remove cryptococci from the host. For example, most cats treated with ITZ alone require a median of 8 months of therapy.⁴² Having observed disease recurrences as long as 10 years after apparently successful therapy, the authors now recommend continuing antifungal therapy until the cryptococcal antigen titer is zero. In some cases, this may take quite a considerable time, possibly up to 2 years or more. In these circumstances, usually only one drug is prescribed, and in some situations KTZ may be used instead of ITZ or FCZ because it is less expensive. Patients that have received a large cumulative dose of AMB in concert with FCY typically require a shorter duration of therapy, presumably because this combination is fungicidal, and residual antigen titers reflect dead fungus undergoing phagocytosis. In cats that are FeLV or FIV positive, it may be prudent to continue maintenance therapy with ITZ or KTZ indefinitely, even if the titer decreases to 0, and the same may be true for German shepherd dogs. Alternatively, the titer can be monitored regularly, perhaps every 6 months, so that any recurrence is diagnosed early. In studies in HIV-infected people with cryptococcosis, persistent infection has been attributed to relapse rather than reinfection or antifungal drug resistance.¹¹

61.7.3.5 Therapeutic Perspective

The diagnosis and treatment of cats and dogs with cryptococcosis remains a challenge. A high index of suspicion for this disease is required, especially in cases with nasal cavity or neurologic disease, because early diagnosis markedly improves outcomes. The cost of therapy is likely to decline over time as the new azoles come out of patent, while new formulations of AMB using delivery systems such as liposomes or lipid emulsions will further improve the prognosis. Although well documented trials have yet to be conducted, many infectious disease physicians consider liposomal AMB to be a useful advance over the deoxycholate formulation, owing to comparable efficacy, reduced toxicity, and thus a greater therapeutic index. Unfortunately the very high cost of this formulation makes it difficult to use in a veterinary setting, even in cats, because cost-efficient strategies to use the contents of a reconstituted vial have not been developed.

597

598

61.8 PUBLIC HEALTH CONSIDERATIONS

Cryptococcosis is the most important opportunistic fungal infection of people infected with HIV. Cryptococcosis is not considered to be a zoonotic disease, so infected cats and dogs pose no public health threat to owners or veterinarians.⁴⁰ The organism does not aerosolize from sites of tissue infection, so the disease cannot spread among people or animals. The major public health significance of infected pets is that they may act as a sentinel species for human beings. In the diagnostic laboratory, culture of *Cryptococcus* is not a health hazard, because only the yeast form is grown routinely, and this form does not aerosolize from media. During handling of the yeast or infected tissues, precautions should be taken to prevent inadvertent inoculation of the organism directly into the body, which has produced infection in experimental animals.

62 CHAPTER 62 Coccidioidomycosis and Paracoccidioidomycosis

Russell T. Greene

62.1 COCCIDIOIDOMYCOSIS

62.1.1 Etiology

Coccidioides is a soil-borne fungus restricted to certain geographic regions. It grows in soil and culture medium as a mycelium. Unlike other fungal pathogens, *Coccidioides* is a haploid organism with no known sexual state.¹⁶ The vegetative mycelia germinates to form thick-walled, barrel-shaped, rectangular, multinucleate arthroconidia, 2 to 4 µm wide and 3 to 10 µm long (Fig. 62-1). Within the mycelium, viable arthroconidia alternate with smaller, thin-walled, nonviable cells and can persist within the soil indefinitely. Activities that disturb the soil cause the intervening nonviable cells to degenerate, releasing the environmentally resistant arthroconidia, which are dispersed by wind. The arthroconidia can germinate to yield new hyphae or serve as the infecting form for animals and people (Fig. 62-2). When inhaled, arthroconidia, at higher temperature (37° C [98.6° F]) and in the presence of increased carbon dioxide, convert into a different morphologic form. They shed all but one nucleus, round up, and enlarge to produce an immature spherule. The nucleus undergoes division, which is followed by inward partitioning of the cytoplasm, resulting in a mature spherule with endospores in the center. The spherule gradually enlarges to 20 to 200 µm in diameter and eventually breaks open to release 200 to 300 endospores (3 to 5 µm). These endospores form new spherules at 37° C or mycelia at room temperature. Transformation from arthroconidia to immature spherules can be completed within 2 to 3 days. Intact spherules are poorly chemotactic for neutrophils. The neutrophils that do attach cannot penetrate the wall of the spherule (Fig. 62-3). However, the endospores are the most vulnerable stage of *Coccidioides* in the body. They attract a large number of neutrophils and are small enough to be phagocytized.

62.1.2 Epidemiology

The mycelial phase of *Coccidioides* has been found in nature only in a specific ecologic region, the Lower Sonoran life zone. Geographically, the Lower Sonoran life zone is within the southwestern United States, Mexico, and Central and South America (Guatemala, Honduras, Colombia, Venezuela, Paraguay, and Argentina) (Fig. 62-4). This zone is characterized by sandy, alkaline soils, high environmental temperatures (summer mean above 26.6° C [79.9° F]; winter mean 4° to 12° C [39.2° to 53.6° F]), low annual rainfall (3 to 20 inches), and low elevation (sea level to a few hundred feet). During prolonged periods of high temperature and low soil moisture, *Coccidioides* survives below the soil surface at depths as great as 20 cm where competitive organisms are few. After a period of rainfall, *Coccidioides* replicates in the upper soil surface, sporulates, and releases a large number of arthroconidia to be disseminated by the wind. Epidemics in people have occurred after dust storms, following the rainy season, or after earthquakes.⁵² People and animals residing in or visiting endemic areas are at high risk of exposure during these periods. Endemically, the incidence of disease is highest in the early fall and winter, when the soil is dry and crops are being harvested. Occupational and recreational exposure of people and animals in the outdoors leads to a greater risk of infection. In the United States, the disease is often referred to as *valley fever* after the occurrence of an epidemic in the San Joaquin Valley of California, but it is also prevalent in Arizona and southwestern Texas. The disease is less common in New Mexico, Nevada, and Utah. A few endemic areas are found in Central and South America, particularly Venezuela. From a taxonomic perspective, *Coccidioides immitis* is the species of organism

599

Infectious Diseases of the Dog and Cat, 3rd Edition

distributed in the San Joaquin Valley, while *Coccidioides posadasii*, formerly the non-California isolate, is found in all other endemic areas.²⁰

Fig 62-1 Lactophenol cotton blue preparation from a *Coccidioides immitis* colony. The arrangement of the barrel-shaped arthroconidia of *C. immitis* is a characteristic alternating pattern of live and dead arthroconidia. These arthroconidia are extremely dangerous, and mycelial cultures should only be handled within a biosafety hood (×100). (Courtesy University of Georgia, Athens, Ga.)

Although the majority of infections in animals and people are diagnosed within the southwestern United States, an occasional case may be identified outside this area. Usually, individuals involved in these “stray” cases have a history of residence or travel within an endemic area. The patient may have been in an endemic area several years earlier, and the organism had remained dormant for some time period.¹⁰ Serologic surveys indicate that most human and canine inhabitants in endemic areas become infected; however, most infections are subclinical or cause only mild, transient respiratory signs. Estimates are that only 40% of infected people develop respiratory symptoms, and very few develop systemic manifestations. In the remaining 60%, the only evidence of infection is seroconversion. Although not proven, the theory suggests that the same statistics concerning infections and clinical signs are similar in domestic animals. In contrast to other species, dogs appear more susceptible to developing disseminated disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.3 Pathogenesis

The disease is highly infectious, but not typically contagious. The major route of infection is by inhalation. Very few (fewer than 10) arthroconidia must be inhaled to produce disease. The incubation period from inhalation to onset of abnormal respiratory signs is 1 to 3 weeks. Primary localized infection of skin lesions from penetrating wounds has rarely been reported. Experimentally, intradermal inoculation or skin scarification produces only localized infection in a small percentage of animals. After inhalation, the arthroconidia first enter the bronchioles and alveoli and then extend into the peribronchiolar tissue, eventually causing subpleural lesions. The first cellular response is neutrophilic, followed by monocytes, lymphocytes, and plasma cells. As with all fungal infections, cell-mediated immunity (CMI) is more important than humoral immunity is in eliminating infection. Mononuclear phagocytes are responsible for removing the organism from tissues and body fluids. Endospores are most susceptible to host CMI. The wall of spherules provides a means of immune evasion by the organism. Although not protective, antibody response to two different antigens of the fungus has been used to detect infection (see Diagnosis).

Recovery from initial infection in people results in lifelong immunity, but resistance to reinfection in animals is uncertain. With massive exposure, pregnancy, or depressed cellular immunity, pulmonary infection can become more extensive, and the organism can invade the hilar lymph nodes and distant tissues. Interleukin levels may play a role in resistance to infection, as has been demonstrated in mice.¹⁹ In people, race is a known risk factor,⁴⁶ but no definite breed predilection has been defined in dogs. In one report,⁵⁰ the authors stated greyhounds may be more susceptible.

If disease progresses beyond the hilar lymph nodes, which it can do within 10 days of exposure, it is considered to have disseminated. Dissemination involves the reproductive cycle from spherules to endospores to new spherules. If the disease disseminates, the organs that are usually affected are, in decreasing order of frequency, bones, eyes, heart and pericardium, testicles, brain, spinal cord, and visceral organs (primarily spleen, liver, and kidney). Ocular lesions begin as a chorioretinitis and extend into the anterior chamber. The intestinal mucosa and endocardium are rarely affected. Virtually all other tissues can be affected. Signs referable to dissemination usually occur approximately 4 months after pulmonary signs develop, but this period is variable, and the respiratory infection may have never been noticed. Disseminated cases usually follow a chronic course of months to years. However, the author has seen disseminated disease in a puppy only 10 weeks of age.

Widespread dissemination was also observed in a dog with concurrent multicentric lymphosarcoma.³⁰

Intrauterine transmission has typically been thought not to occur because of the large size of the spherules. Neonatal disease transmission has generally been thought to occur from contact of the neonate with the female genital tract or vaginal secretions as the neonate is being born. However, in a case report in a human infant delivered by cesarean section, transplacental transmission from mother to baby was well documented.¹¹ This baby girl developed disease at 15 days of age.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 62-2 Life cycle of *C. immitis*. **A**, In the soil (an arthroconidium) or in culture of infected tissues (an endospore), the single cell germinates to become hyphae, which eventually form arthroconidia that alternate into becoming live and dead cells. The hyphae can break off at the nonviable segments, releasing arthroconidia that can disseminate in the air or enter the soil to form new hyphae. **B to E**, Once airborne arthroconidia are inhaled, they enter the lung and change morphologically to a round spherule that undergoes repeated internal divisions until it is filled with thousands of endospores. Each endospore has the capacity to become a new spherule. **F**, They also disseminate via phagocytes to infect distant tissues, causing granuloma formation. **G**, Swelling and drainage occur at lesion sites close to skin surfaces and underlying infected bone. **H**, Regional lymph nodes draining sites of infection become enlarged. (Courtesy University of Georgia, Athens, Ga.)

Fig 62-3 Spherule of *C. immitis* containing visible endospores as observed on cytologic examination. **A**, Note the pyogranulomatous inflammation consisting of neutrophils and macrophages surrounding the spherule (Wright, $\times 20$). **B**, Similar magnification of a free spherule in an inflammatory exudate (Wright, $\times 1000$). (Courtesy University of Georgia, Athens, Ga.)

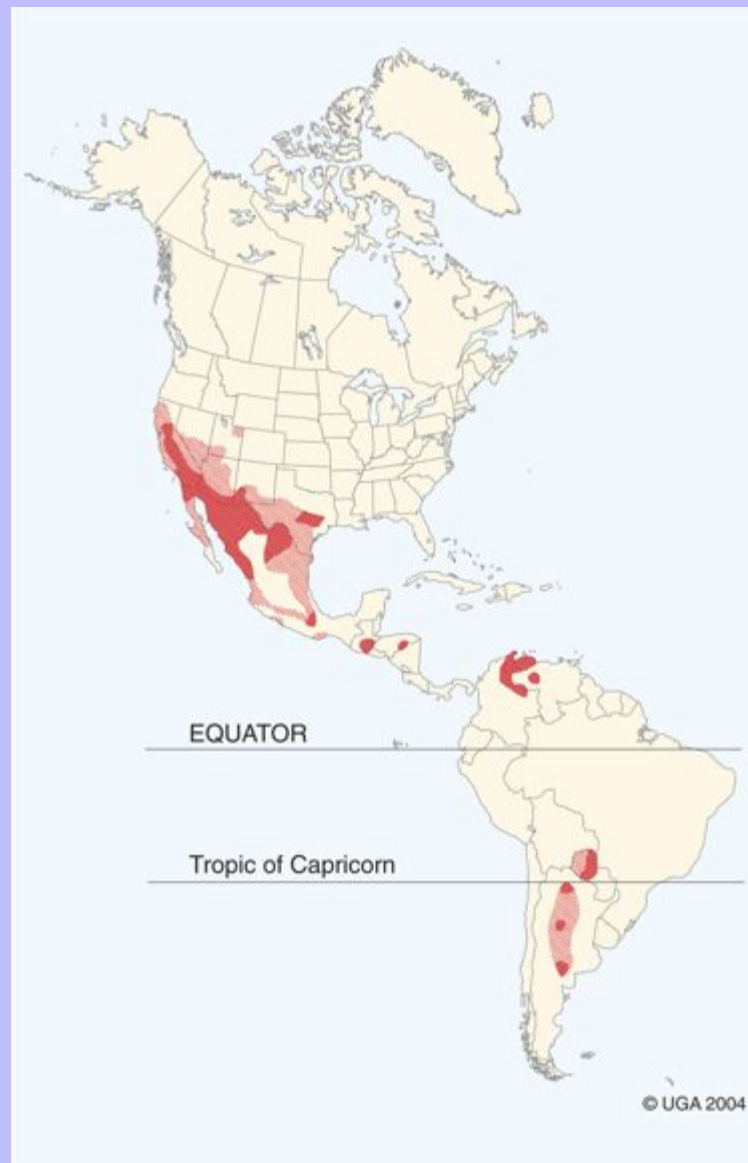

Fig 62-4 Worldwide distribution of incidence and prevalence of coccidioidomycosis. The areas marked by horizontal lines indicate incidence; the cross-hatched areas indicate regions of high endemicity. (Courtesy University of Georgia, Athens, Ga.)

Although very rare, reports have surfaced of *C. immitis* fungal hyphae, rather than endospores or spherules, being recovered from disseminated infections involving the central nervous system (CNS) in people.^{42,61} In

Infectious Diseases of the Dog and Cat, 3rd Edition

many instances, but not always, this type of infection has been found in association with a surgically placed CNS shunt for hydrocephalus.²⁹ This unusual form of infection has not been reported in animals.

62.1.4 Clinical Findings

62.1.4.1 Dogs

The high prevalence of positive skin test reactions in epidemiologic surveys of healthy dogs indicates that the most common form of coccidioidomycosis is an asymptomatic or mild, undiagnosed, lower respiratory tract infection. When clinical respiratory disease develops, it can be characterized by either a dry, harsh cough similar to that associated with tracheobronchitis or a wet, moist, productive cough. A dry cough is usually the result of hilar lymphadenomegaly or diffuse pulmonary interstitial disease. A productive cough is usually the result of alveolar involvement. Fever, partial anorexia, and weight loss are commonly present in both situations. The pulmonary disease can resolve or worsen. The latter course leads to severe generalized pneumonia with a worsening of respiratory signs.

Clinical signs most commonly associated with disseminated disease include, in decreasing order of frequency, persistent or fluctuating fever, anorexia, weight loss, depression and weakness, lameness, localized peripheral lymphadenomegaly, draining skin lesions, seizures, bone or paraspinal hyperesthesia, keratitis, uveitis, and acute blindness. Gastrointestinal (GI) signs, as well as generalized peripheral lymphadenomegaly, are extremely uncommon. Other systemic lesions are common in dogs in endemic areas. The occurrence of clinical signs relative to each organ system depends on the specific localization of infection and is reviewed here.

Signs of right- or left-sided congestive heart failure can also occur. Cardiac dysfunction arises from disturbances in blood flow, conduction, and myocardial contractility resulting from granulomatous lesions in the pericardium.⁵⁵ The lesion often spreads within the pericardial sac, resulting in constrictive pericarditis.

Cranial or paraspinal hyperesthesia is typical for dogs with early CNS localization as a result of meningeal localization and inflammation.³² Seizures, ataxia, behavioral changes, and coma have been associated with subsequent encroachment on the CNS by granulomatous meningoencephalomyelitis.⁷

Lameness is usually accompanied by painful bone swellings (Fig. 62-5). Bone lesions usually are initially localized to one bone but may progress to involve multiple sites. The lesions generally occur in the long bones in the distal diaphysis, metaphysis, and epiphysis, and a combination of bony lysis and production is usually noted. Lesions occur in the axial skeleton but only at a 10% prevalence compared with the appendicular skeleton. Joint infection is not typical, although secondary immune-mediated polyarthritis can develop in infected dogs.

Most cutaneous involvement results from systemic hematogenous spread of the organism. Skin lesions that begin as small bumps and progress to abscesses, ulcers, or draining tracts are almost always found over sites of infected bone (see Fig. 62-5). Naturally occurring primary cutaneous infection from penetrating injury is extremely rare in dogs.⁴⁸

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.4.2 Cats

Signs associated with *C. immitis* infection in cats are similar to those described in dogs.²⁸ However, skin lesions are the most frequent type of infection found in cats. Skin infections without underlying bone involvement is common. Fever, inappetence, and weight loss are commonly found concurrently with skin lesions. Coughing, wheezing, and respiratory difficulties are only occasionally recognized with feline *C. immitis* infections, possibly because cats limit their physical activity. Appendicular bone lesions, similar to lung lesions, are rarely recognized in feline infections compared with canine infections. When bone lesions are present in cats, the radiographic changes are similar to those observed in dogs. Ocular lesions of chorioretinitis and anterior uveitis occur with about the same frequency in cats as they do in dogs.

62.1.5 Diagnosis

62.1.5.1 Clinical Laboratory Findings

Hematologic changes may include mild nonregenerative anemia and moderate neutrophilic leukocytosis, often with a left shift and monocytosis. Eosinophilia of blood and cerebro-spinal fluid (CSF), common in human coccidioidomycosis, is quite variable in animals. Hyperglobulinemia and hypoalbuminemia are common, reflecting a chronic persistent inflammatory disease. Hypercalcemia unassociated with bone lesions has not yet been described in affected dogs or cats but has been found with other systemic mycoses and in some human patients. An osteotropic factor similar to that causing humoral hypercalcemia of malignancy has been postulated.

601

602

Fig 62-5 Two dogs with disseminated coccidioidomycosis with evidence of osteomyelitis. **A**, One dog with left carpal swelling had a draining fistula, and **(B)** the second dog had bilateral tarsal swelling. (Courtesy University of Georgia, Athens, Ga.)

Fig 62-6 Lateral thoracic radiograph of a dog with pulmonary coccidioidomycosis, showing a hilar lymphadenomegaly and diffuse interstitial lung pattern. (Courtesy Russell T. Greene, Phoenix Veterinary IM Services, Phoenix, AZ.)

62.1.5.2 Radiography

Thoracic radiographic findings vary with the severity of the disease. A diffuse interstitial pattern is most common but is often mixed with a localized alveolar pattern (Fig. 62-6). Miliary to nodular interstitial densities may be found. If solitary nodules are found, they are often found in the periphery. If computed tomographic scans are used for evaluation of these nodules, central necrosis or cavitation may be found in up to 30% of the lesions.³⁵ A halo of homogeneous attenuation around the nodule is often found. Pulmonary abscess formation, fibrosis, and bronchiectasis (rarely calcification) may be sequelae to severe pulmonary infection. Hilar lymphadenomegaly is quite common, affecting most dogs with chronic illness, but calcification of the hilar lymph nodes or sternal lymphadenomegaly is rare. Pericardial and pleural effusion may occur secondary to right-sided myocardial failure or, more frequently, to pericarditis.⁵⁵ Radiographic findings of osteomyelitis are typically a mixture of both lysis and production (Fig. 62-7).

Fig 62-7 Radiograph of the distal humerus of a dog with disseminated coccidioidomycosis. Lesions are classically a mixture of lysis and production of bone. (Courtesy University of Georgia, Athens, Ga.)

Reports of magnetic resonance imaging (MRI) changes in animals are lacking. In people with acute meningitis, if MRI is performed, focal or diffuse enhancement may be found along with ventricular enlargement and deep infarcts.¹⁸

62.1.5.3

Cytology

Coccidioidomycosis is conclusively diagnosed by cytologic or histologic visualization of the organism. However, because of lesion localization or costs associated with invasive procedures, demonstration of the organism is often not possible. In such cases, a diagnosis is based on history, clinical findings, and serologic test results.

As with other nodular interstitial diseases, false-negative results are common with transtracheal or bronchial washings. The chance of a positive yield increases if alveolar disease is present. In human patients with diffuse lung disease, Papanicolaou's (Pap) stain was found to be superior in detecting organisms compared with 10% potassium hydroxide or calcofluor white.⁵¹ Spherules are frequently found in aspirates of enlarged nodes or in impression smears of draining lesions (Fig. 62-8). CSF abnormalities include pleocytosis with a

602

603

Infectious Diseases of the Dog and Cat, 3rd Edition

predominance of neutrophils and a lesser number of mononuclear cells and are consistent with granulomatous inflammation. Organisms may not always be observed.

Fig 62-8 Histopathology of *C. immitis*-induced lesion with a large *C. immitis* spherule surrounded by pyogranulomatous inflammation (H and E stain, $\times 100$).

The organism can be seen in unstained preparations under reduced light as a large (10 to 80 μm), round, double-walled structure containing endospores. Ten percent potassium hydroxide can clear an unstained specimen, although stained preparations are more typical. The organism is readily recognized with standard Wright's stain, but to specifically stain the fungal structures, the best stains are Pap and periodic acid-Schiff (PAS). With Pap stain, the capsular wall is refractile and purple-black, the cytoplasm yellow, and the endospores red-brown. Not all spherules contain recognizable endospores. Smaller spherules may have a crumpled, transparent wall. With PAS stain, the wall is deep red to purple and the endospores are bright red. A large number of neutrophils may surround the spherules, making visualization difficult.

62.1.5.4

Biopsy

In histopathology specimens, the organism usually can best be found in microabscesses. Spherules are detected employing routine hematoxylin and eosin stains, but for optimal visualization, special stains such as PAS or Grocott-Gomori's methenamine silver should be used. Spherules may be difficult to find in bone biopsy samples because of the reactive bone that forms within lesions. Repeated biopsies may be necessary to find the organism. Pathologists recommend that several biopsy samples be taken from the same lesion. Redirecting the biopsy needle through the same insertion site to obtain several core samples is often most successful. Immunofluorescence techniques can also be used to identify *C. immitis* spherules in tissues or cytologic preparations, but false-negative results can occur, and these techniques are rarely needed.

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.5.5 Fungal Isolation

C. immitis grows on a wide range of common fungal culture media and blood agar. *No* attempts should be made to culture and identify this organism within veterinary practices. Instead, samples should be sent to laboratories familiar with biosafety precautions (see [Appendix 5](#), Laboratory Testing for Infectious Diseases in Dogs and Cats). The mycelial phase grows best at 25° to 30° C. It usually grows within 3 days but may require more time if the number of organisms in the sample is low. The characteristic pattern of alternating live and dead arthroconidia associated with the appearance of the fungal colony allows for presumptive identification, but additional in vitro and in vivo methods can further definitively identify the organism. Veterinarians, technicians, and laboratory personnel must recognize that arthroconidia from mycelial growth are highly infectious.

62.1.5.6 Serologic Testing

62.1.5.6.1 Dogs

When the organism cannot be demonstrated by cytology or biopsy, detection of antibodies to the organism is commonly used as a presumptive test. The two classic antigens for serotesting are the tube precipitin (TP) and complement fixation (CF) antigens. The names for these differently prepared antigens were based on the types of tests that were initially used to detect antibodies. The antibody response to the TP antigen is primarily immunoglobulin (IgM), whereas the antibody response to the CF antigen is associated more with IgG. For interpretation of TP and CF antibody titers in naturally infected dogs, refer to [Table 62-1](#). Refer to [Appendix 5](#) for laboratories that perform these tests.

Advances in molecular diagnostics have brought new methods of antibody detection. For example, use of a purified recombinant proline-rich antigen of *Coccidioides* was used to detect infection and monitor progress of disease in people.⁴⁵ Clinicians should always check with the laboratory performing the serologic tests to determine which method is being used. Instead of the TP and CF methods, some laboratories employ the latex agglutination, agar gel immunodiffusion (AGID), or enzyme-linked immunosorbent assay (ELISA) methods for detection of these same antibodies. See [Table 62-2](#) for a comparison of these methods. TP and CF antigens are still used in performing the AGID tests. Because the antigens and the antibody responses were named well before these newer techniques, the serologic terminology becomes confusing. Even more confusing is the fact that many of these new assays have not been fully evaluated using animal sera. Assumptions have often been made concerning their accuracy based on limited research in testing human sera. Because of the nature of the disease and the studies that have been completed to date, determining which of the tests are correct versus incorrect is usually difficult when discrepancies are noted. Further serologic studies with corresponding histologic, cytologic, or mycologic confirmation are needed. Advantages of the AGID and the ELISA methods over the classic CF test are that these newer methods are less complicated to perform, and interference by anticomplementary factors, which can be found in 15% to 25% of normal dog sera, does not occur.

Negative serologic test results, despite microbiologically confirmed coccidioidomycosis, occur on occasion. A published series of cases in people have suggested a prevalence of up to 15% to 20%. The author's opinion is that a 5% to 10% prevalence rate is more typical for dogs. In many cases, dermatologic cases and primary hilar lymphadenopathy cases are the ones that tend to have seronegative results.²⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Tests to detect antigenemia in people have been developed and used on an investigational basis in rodents. Antigen detection would be helpful in early cases before seroconversion or in patients with immunodeficiencies in which seroreactivity does not develop. Interference by various components in serum has been a major problem with antigen tests. However, newer techniques are being evaluated.

603

[Appendix 5](#) should be consulted for a list of laboratories that perform these serologic tests for coccidioidomycosis.

605

Table 62-1 Interpretation of Serologic Testing for Coccidioidomycosis in Dogs and Cats

	TP ANTIBODY: NEGATIVE	TP ANTIBODY: POSITIVE (PREDOMINANTLY IgM)
CF ANTIBODY: NEGATIVE	1. No infection 2. Early infection; if disease suspected, repeat test in 4 to 6 wks to detect positive TP or CF test results 3. Rapidly fatal, fulminating infection in severely immunocompromised animal	1. Early or mild infection: TP test results become positive 2wks postexposure and may become negative after 4 to 6 wks
CF ANTIBODY: POSITIVE (PREDOMINANTLY IGG)	1. Past exposure or disease, healing or localized lesions, or long-standing residual titer (especially if weak CF titer, 1:4 or less) 2. Chronic infection: TP antibody frequently disappears after 4 to 6 wks; the higher the CF titer, the more likelihood of severe or disseminated disease 3. Higher CF titers = 1:64 are most frequently seen with severe pulmonary or disseminated lesions	1. Early or active infection: the greater the CF titer, the more likely disease is severe or disseminated 2. Chronic infection: positive TP tests occur later in infections or at the time of dissemination or recrudescence

TP, Tube precipitin; CF, complement fixation.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 62-2 Comparison of Serologic Tests for Coccidioidomycosis^a

TEST (ABBREVIATION)	MEASURED IMMUNOGLOBULIN	COMMENTS
TP	IgM	Positive results early in disease. Titer may increase with reactivation or dissemination.
CF	IgG	Good test for quantitative titers. Considered reference test for IgG. Positive results occur later in infection and rise with dissemination. Titer remains elevated months after successful treatment or if arrested. Titer gradually decreases with successful treatment. False-negative results occur in some immunosuppressed or anergic animals.
Latex agglutination	IgM	Some false-positives occur in canine sera. Detects acute (<1 mo) infections.
Immunodiffusion (AGID) TP antigen (IDTP)	IgM	More sensitive than TP in detecting recent (<1 mo) infections.
CF antigen (IDCF)	IgG	Good correlation with ELISA IgG with quantitative immunodiffusion. Most sensitive screening test for IgG.
ELISA		
IgM	IgM	Some (~15%) false-positives when compared with IDTP; also cross-reacts with some blastomycosis sera.
IgG	IgG	Good correlation with CF and IDCF: OD readings do not always correlate directly with CF titers. Cross-reacts with some blastomycosis sera.

TP, Tube precipitin; CF, complement fixation; AGID, agar gel immunodiffusion; IDTP, immunodiffusion tube precipitin; IDCF, immunodiffusion complement fixation; ELISA, enzyme-linked immunosorbent assay; OD, optical density.

a Based on data from Greene RT, unpublished observations, 1996; Pappagianis D, Zimmer BL. 1990. *Clin Microb Rev* 3:247–268.

62.1.5.6.2

Cats

Early publications suggest that serologic tests were not useful diagnostic aids. However, a review of 48 feline cases indicated that both TP and CF antibodies were routinely detected in feline infections.²⁸ Both antibodies appear to persist for long periods in cats, even when therapy is initiated and maintained.

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.5.7 Skin Testing

Skin testing is used for epidemiologic surveys and evaluation of immunocompetence to *C. immitis* rather than as a diagnostic tool. The accuracy of intradermal testing with coccidioidin is subject to antigen variability. A positive reaction is defined as an area of induration of 5 mm or greater at 24 to 36 hours after injection. A positive test result indicates past or present infection. In people, the test result becomes positive within 1 week, after development of respiratory signs, whereas in dogs, a positive test result has been found within 3 to 8 weeks of natural exposure. In healthy people, positive skin test result indicates past exposure and resistance to infection and remains positive for years. Approximately 5% of people and 10% of dogs with disseminated disease have a negative skin test results, owing to severe immunosuppression. Skin testing is not especially specific because cross-reactions with histoplasmin and blastomycin can occur. Use of an antigen from the spherule phase, spherulin, has not proven diagnostically superior to coccidioidin in people.

62.1.6 Pathologic Findings

The lesions induced by *C. immitis* in dogs and cats are usually pyogranulomatous and are most often seen in the lungs. On gross inspection, lesions may vary from miliary to massive, from red to gray to white, from nodular to diffuse, and from firm to caseous or liquefactive (Fig. 62-9). Tracheobronchial lymph nodes are often increased in size and firm. Bone enlargement is found in dogs with coccidioidal osteomyelitis. At the time bone lesions are observed, lung lesions may have resolved. With CNS involvement, granulomas have been found in the cerebrum, midbrain, and cord. A granulomatous uveitis, retinitis, and keratitis may be present. In dogs with granulomatous pericarditis, the organism can be found in pericardial fluid. In dogs, right-sided heart failure is more commonly caused by coccidioidal pericarditis than by myocarditis. Fungal spherules can be found within granulomatous lesions.

Fig 62-9 Lungs from dogs with severe pulmonary coccidioidomycosis showing (A) markedly enlarged hilar lymph node and (B) multiple light-colored granulomas throughout the lung lobes. (A, courtesy Russell T. Greene, Phoenix Veterinary IM Services, Phoenix, AZ; B, courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.7 Therapy

Because of the lack of controlled studies and the wide range of disease manifestations, ranging from spontaneously clearing uncomplicated illness to aggressive disseminated illness, the standard of care for treatment of coccidioidomycosis has not been fully defined.³⁴ Therapy in dogs and cats typically involves long-term antifungal drug treatment (Table 62-3). However, success is unpredictable. Controversy exists as to whether animals with primary pulmonary disease should be treated because these cases may resolve spontaneously. In people with initial mild primary pulmonary involvement, therapy is avoided unless chronic (6 weeks' duration) debilitation is present.²² In dogs and cats, therapy has generally been instituted earlier for fear of dissemination. Animals with severe pulmonary infections, those with increasing titers of CF antibody (especially at or above 1:16), and those with fever, weakness, lameness, or worsening clinical signs are candidates for therapy. All animals with disseminated disease should be treated.

Because of the cost and potential toxicity of treatment, caution should be exercised when a diagnosis is based on serologic data alone. Positive CF titers of 1:8 or less are suspect for infection in animals. Patients with clinical illness may be treated, and serotesting should be repeated in 3 to 4 weeks to determine whether the titer is rising. Many dogs in enzootic areas have titers of 1:4 or less from prior exposure. Symptomatic animals with these low titers should have additional diagnostic procedures performed rather than be treated. Although relatively infrequent, animals can be infected yet be seronegative.

Deciding whether to terminate therapy is based on resolution of the clinical disease, radiographic appearance of bone and lung lesions, and serologic titers. Serologic titers alone may not be helpful in determining whether the disease is in remission because CF titers may stabilize or decrease only slightly. However, long-term monitoring of serologic response is beneficial to determine whether the titer is rising. Rising titers suggest poor absorption of drug or poor therapeutic response. If blood levels of the drug suggest adequate absorption, an alternate therapy should be considered.

If uveitis is the only sign of active infection, and it is not improving with antifungal therapy, enucleation should be performed. Uveitis has been curative, without further treatment, in at least one cat.²⁸

The three azole drugs, ketoconazole (KTZ), itraconazole (ITZ), and fluconazole (FCZ), are most commonly prescribed. Because of the marked drop in cost of the newer azoles (ITZ and FCZ) when prepared by compounding pharmacies, these drugs are increasingly being used as the first drugs of choice in small animals. Although, no small-animal studies have been done that demonstrate a superiority of outcome in patients treated with these drugs, side effects with them tend to be fewer. FCZ is thought to have the best tissue penetration and the fewest side effects and is recommended for meningeal coccidioidomycosis. Interestingly, a recent randomized, double-blind comparison study between ITZ and FCZ in people with nonmeningeal coccidioidomycosis was completed.²³ It compared response rates in people with pulmonary, soft-tissue and skeletal lesions, when treated with either drug for 8 months. This excellent study showed no statistical difference between the efficacy of ITZ or FCZ. However, patients treated with ITZ tended to do better. This tendency for better success was most pronounced in people with skeletal lesions. Of interest was the relapse rate of approximately 15% of patients after these drugs were discontinued. Possibly, these patients needed to receive more than 6 months of therapy to prevent a relapse.

605

606

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 62-3 Antifungal Therapy of Coccidioidomycosis

DRUG ^a	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (MONTHS)
Ketoconazole	D	5–10 mg/kg	PO	12	8–12 ^c
	C	50 mg (total)	PO	12–24	^c
Itraconazole	D	5 mg/kg	PO	12	^c
	C	25–50 mg (total)	PO	12–24	^c
Fluconazole	D	5 mg/kg	PO	12	^c
	C	25–50 mg (total)	PO	12–24	^c
Amphotericin B ^d	D	0.4–0.5 mg/kg	IV	48–72 ^e	^f
Lufenuron	D	5 mg/kg	PO	24	4 ^g

D, Dog; C, cat; PO, by mouth; IV, intravenous.

- a For additional information, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c Not based on controlled studies, but typical duration with dissemination is generally 12 months. Primary respiratory diseases often require shorter therapy. Ketoconazole or itraconazole have been the drugs of choice for treating dogs, and itraconazole has been preferred in treating cats.
- d Amphotericin is rarely used because of its nephrotoxicity. It can be used alone or in combination with an azole. If used in combination, the recommended cumulative dose is often one half. The newer lipid encapsulated amphotericin B preparations are less toxic, but ideal dosages and intervals have not been determined.
- e Given Monday and Thursday or Monday, Wednesday, and Friday (i.e., two to three times weekly).
- f Until cumulative dose is 8 to 11 mg/kg.
- g Efficacy of therapy and minimum dosage regimen has not been established. Maintenance therapy may be needed for longer periods. This treatment is still experimental and not generally recommended by the author.

Using these drugs for 3 to 6 months beyond resolution of clinical signs and normalization of serologic titers is standard. As in people, how low the titer should go and how long the course of therapy should be to prevent relapses is controversial and undetermined.^{44,58}

62.1.7.1 Ketoconazole

The drug of choice for initial treatment of coccidioidomycosis in dogs has been KTZ. See the Drug Formulary, [Appendix 8](#), for detailed information about this drug. The recommended dosages for KTZ are listed in [Table 62-3](#). The duration of therapy has been variable, depending on the site and extent of disease. Relapses are common if the drug is not administered on a daily basis for an adequate period. Treatment of animals with bone or disseminated coccidioidomycosis typically requires a minimum of 1 year of therapy. Because GI absorption of the drug is variable, measuring a 2- to 4-hour postpill KTZ blood level after 2 to 3 weeks of treatment is helpful. An acidic gastric environment increases the absorption of KTZ; therefore a dose of vitamin C is often concurrently administered.

Infectious Diseases of the Dog and Cat, 3rd Edition

Poor response and relapses sometimes occur with KTZ. Serologic tests should be repeated after 4 to 6 weeks of therapy. If the CF titer has continued to rise or clinical signs are deteriorating, an alternative azole or, rarely, amphotericin B (AMB) should be considered (see [Table 62-3](#)).

In people with nonmeningeal coccidioidomycosis, KTZ appears to be fungistatic; most patients improve, but relapses are common even at higher-than-recommended doses, and cures occur in only approximately 30% of patients. For meningeal disease, KTZ has been considered a poor choice for treatment because of its decreased penetration into the CSF and CNS. In the past, intrathecal AMB was given for CNS coccidioidomycosis, but the drug is irritating by this route. Because of its excellent pharmacokinetics and CNS penetration, FCZ is recommended for these cases (see Fluconazole, [Chapter 57](#), and Drug Formulary, [Appendix 8](#)).

62.1.7.2 Itraconazole and Fluconazole

The newer azoles, ITZ and FCZ, are thought to have fewer side effects and to be more efficacious for treating coccidioidomycosis in people as compared with KTZ; however, no controlled studies in dogs or cats demonstrating similar efficacy have been conducted. Cats generally tolerate ITZ better than they do KTZ, with fewer side effects. A multiinstitutional, randomized, double-blind study evaluating the efficacy of FCZ and ITZ in nonmeningeal *Coccidioides* infections revealed a trend towards greater efficacy with ITZ as compared with FCZ, especially if skeletal lesions were involved.²³ Concern has surfaced that a high relapse rate (40%) may occur in human patients following discontinuation of FCZ therapy, which was higher than that noted for ITZ therapy. In some patients, the newer azoles have failed when they were tried first only to have the infection subsequently controlled with KTZ. As with KTZ, some of the animals treated with ITZ or FCZ develop relapses. These drugs may be an alternative to KTZ but not a panacea. Side effects such as hepatic dysfunction, GI upsets, and skin reactions⁴⁸ can also occur, as they do with KTZ. Hypertriglyceridemia has been seen with itraconazole.⁶⁰ An acidic gastric environment is not needed for FCZ absorption.

606

Although expense is a major concern for the use of azoles, compounding pharmacies in the United States currently formulate capsules at a reasonable cost. Newer formulations of ITZ, as an oral solution with the carrier cyclodextrin, appear to confer increased bioavailability.

607

62.1.7.3 Other Triazoles

Novel triazole compounds, such as voriconazole have become available for treating resistant infections, and posaconazole (SCH 56592), UR-9746, and UR-9751 are being developed. These have been evaluated in vitro and in experimental models of coccidioidomycosis.¹

* References: 8, 15, 25, 40, 43.

62.1.7.4 Amphotericin B

For many years, AMB was the only antifungal drug available; however, because of its potential renal toxicities and need for intravenous administration, it is currently less commonly used. The newer route of subcutaneous administration has not been evaluated in this disease (see Drug Formulary, [Appendix 8](#)). Now, new lipid-encapsulated formulations of AMB are on the market, with reportedly fewer renal complications,

Infectious Diseases of the Dog and Cat, 3rd Edition

that have been used in treating human patients,³ but their exact efficacy and optimal dosages have not been determined for dogs and cats. In a dog with concurrent multicentric lymphoma, simultaneous treatment with lipid formulation of AMB and cytotoxic chemotherapy was successful in producing initial remission of both diseases.³⁰ Other case reports have been issued of the efficacy of lipid-encapsulated formulations of AMB in people with coccidioidomycosis and of dogs and cats with other fungal infections. These lipid-encapsulated formulations of AMB are often cost prohibitive for general use.

Lipid formulations of AMB are available and have less toxicity but have not been clinically tested in dogs or cats (see Drug Formulary, [Appendix 8](#)). In people, case reports with successful outcomes have been issued.³⁷ The drug is indicated as the first choice in treating people with clinically severe pulmonary infections.²² In a rabbit model of meningeal coccidioidomycosis, systemically administered lipid encapsulated AMB led to fungal eradication from brain and spinal cord in 3 out of 8 animals, a result not previously seen with any other systemic therapy studied.¹⁴ Several lipid-encapsulated AMB formulations are commercially available. No study has determined the efficacy of one over the other, but a single case report has been done of a potential anaphylactic reaction in a human patient that started out receiving one compound and then was switched to another one.³³

AMB, previously the drug of choice for treating canine coccidioidomycosis, may be indicated in animals that are unable to tolerate an azole compound. The toxicities and difficulties of administering AMB make it less desirable than are the azoles for dogs (see [Chapter 57](#)). The dose of AMB to induce remission, when used alone or in combination, is listed in [Table 62-3](#). In people, using intrathecal AMB in combination with an oral azole for coccidioidal meningitis is common.⁵⁹ A subcutaneous route of administration has been reported for the treatment of cryptococcosis, but this method of delivery has not been adequately tested on a series of dogs. The author has tried it on a few dogs with bone lesions and the clinical signs remained unchanged.

62.1.7.5

Chitin Synthesis Inhibitors

Chitin synthesis inhibitors are newer antifungal agents that also interfere with formation of the cell wall of fungi. One drug, Nikkomycin-Z (Shaman Pharmaceuticals, Inc., San Francisco, Calif.), is nearing clinical trials. This compound is fungicidal, rather than fungistatic, as are the azoles. By comparison, Nikkomycin-Z requires relatively low doses for shorter time periods; it is orally administered. Lufenuron, another chitin synthesis inhibitor, is licensed for control of flea infestation in dogs and cats. In one pilot canine study, instead of once-monthly treatment, the drug was given daily for 16 weeks.⁵ Clinical improvement began after 1 week, and resolution of radiographic lesions in the lungs was minimal. Dogs that showed some improvement did not start showing any changes until after 10 weeks. The drug did not appear to affect titers, and it has never been shown to be effective for successful treatment of this disease.

Caspofungin, which has received United States Food and Drug Administration approval for salvage therapy of invasive *Aspergillus* infections, is the first of the echinocandins (these inhibit 1,3 β D-glucan synthetase) to become available. Caspofungin was therapeutically effective in a murine model of *C. immitis* infection, despite its lack of in vitro activity against the fungus when minimum inhibitory concentrations were determined, using National Committee of Clinical Laboratory standards.^{24,25} For further information, see Drug Formulary, [Appendix 8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.7.6 Terbinafine

Terbinafine is a naftifine analog with a mechanism of action distinct among antimycotics. It inhibits fungal growth by inhibiting the fungal enzyme squalene epoxidase, a key enzyme in the synthesis of the fungal sterol ergosterol. Terbinafine has a broad range of in vitro activity and distributes widely into adipose and keratin-rich tissues. However, in a rabbit model of coccidioid meningitis, it did not do as well as did FCZ alone, although some attenuation of the lesions was noted. Terbinafine was not detectable in the CSF, suggesting that it did not pass through the blood-brain barrier well. However, this finding was not considered the cause of the poor response because other drugs, such as ITZ, have efficacy in this model but cannot be measured in the CSF. The possibility exists that, in combination with another drug, terbinafine may provide synergistic activity. Further studies will be needed to define the role of this drug in coccidioid infections.

62.1.7.7 Cytokines

Interferon- γ has been used as an adjunct in the treatment of a person with *C. immitis* infection and respiratory failure that failed to respond to conventional therapy alone.³⁹ For a further discussion of use of cytokines in treating disseminated fungal infections, see Antifungal Chemotherapy, [Chapter 57](#).

62.1.7.8 Prognosis

The prognosis for localized respiratory coccidioidomycosis without treatment is good. However, many dogs are routinely treated to decrease the chance of dissemination. Without treatment, dogs with disseminated disease will usually die, or they have to be euthanized shortly after the disease is discovered. In more than 90% of these dogs, signs resolve with KTZ therapy. However, complete recovery rates in animals that require no further maintenance therapy are much lower. Complete recovery rates vary with the severity of the disease and degree of dissemination, ranging from 90% with only pulmonary involvement to 0% with multiple bone involvement. An overall recovery rate of approximately 60% has been noted. CNS involvement has a guarded to poor prognosis because of difficulty of drug penetration. Many infected cats show clinical improvement with KTZ therapy, although relapses have been common, especially when medication was discontinued.^{14,28} Some cats experience a relapse each time that treatment is stopped (i.e., multiple relapses).

62.1.8 Prevention

The most beneficial strategy to prevent infection in people or animals would be through vaccination; however, a commercial vaccine is not available. A killed spherule vaccine was found to be highly protective against coccidioid infection in mice. A similar vaccine in people failed to demonstrate protection. Current studies are examining the use of purified or recombinant antigens as vaccines.^{1,31,54,62}

Evidence suggests that a patient's immune reaction to the organism may protect against dissemination.⁶ Immunotherapy has been tried with little to variable success in people using a variety of drugs and cytokine inducers. Similarly, levamisole and acemannan have been empirically given to infected dogs with little success. All immunosuppressive drugs, including glucocorticoids, should be avoided or withdrawn before and during therapy. Synthetic immunomodulators or those produced by recombinant DNA techniques may offer an approach in the future.

Infectious Diseases of the Dog and Cat, 3rd Edition

62.1.9 Public Health Considerations

Coccidioidomycosis is generally accepted as being noncontagious because the infectious arthroconidial form of the agent is typically not produced in tissues. Except for one unusual case in which disseminated meningeal coccidioidomycosis developed in a veterinarian who performed a necropsy on a horse with disseminated disease,³⁸ no known direct spread from animal to people occurred. This veterinarian may have been exposed to arthroconidia growing in improperly preserved infected tissue or, less likely, to aerosolized or inoculated spherules from fresh tissues or discharges. In general, infected animals are not considered public health hazards. However, veterinarians should be cognizant of the potential problem of placing bandages over draining lesions. The tissue drainage may contaminate the bandage material and provide a suitable environment for arthroconidia development.

In contrast, handling mycelial cultures of the organism in the laboratory is extremely dangerous, and precautions must be taken to prevent arthroconidia release into the air. Laboratory technicians have also developed primary cutaneous lesions while working with the mycelial phase or while injecting suspected cultures into laboratory rodents. *C. immitis* has been considered a potential bioweapon.¹⁷ Considering this organism, the implementation of such use has many limitations, and the efficacy would likely be highly variable.

62.2 PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis, a systemic fungal disease of people and rarely of animals in Central and South America, is caused by the dimorphic fungus *Paracoccidioides brasiliensis*. It is characterized by granulomatous pulmonary and disseminated lesions. The organism was isolated from a dog with cervical lymphadenomegaly. Budding yeasts were surrounded by granulomatous inflammation. The organism was identified by immunochemistry and genetic analysis. This was the first report of the disease in a dog.^{48a}

63 CHAPTER 63 Sporotrichosis

Edmund J. Rosser, Jr.

Robert W. Dunstan

63.1 ETIOLOGY AND EPIDEMIOLOGY

Sporotrichosis is a mycotic disease of animals and people caused by the dimorphic fungus *Sporothrix schenckii*. The fungus exists in a mycelial form at environmental temperatures (25° to 30° C [77° to 86° F]) and in a yeast form at body tissue temperature (37° C [98.6° F]). In the environment the organism changes phases into an ascomycete teleomorph that can survive on living or decaying plant material.⁵⁴ The organism is found worldwide and prefers soils that are rich in decaying organic matter. It has also been isolated from barberry and rose bush thorns, sphagnum moss, tree bark, and mine timbers.^{34,39,48} Sphagnum moss has been associated with sporadic outbreaks of sporotrichosis,¹⁶ including a multistate outbreak among forestry workers and seedling handlers.¹¹ The sphagnum moss was harvested in Wisconsin and used as a packing for conifer seedlings.⁹ *S. schenckii* does not grow on the living sphagnum moss in bogs but does grow and sporulate well on moist, dead sphagnum moss after harvest.⁵⁷ The handling of stored hay bales and moldy hay have also been associated with outbreaks.^{7,10} In addition, some case reports have described sporotrichosis associated with puncture wounds from fish spines, squirrel bites, and the stings of fire ants.^{15,28,42} Many cases in people have related to scratches acquired during armadillo hunting. Infected cats develop many draining lesions and have also been responsible for many infections in people.³

609

Infection is usually caused by traumatic inoculation into tissues of soil, plant material, or organic matter contaminated with the fungus.^{39,48} The disease in dogs is often associated with a puncture wound caused by a thorn or wood splinter and therefore is most frequently observed in hunting dogs. In cats, sporotrichosis is most commonly identified in intact male cats that are allowed to roam outdoors. Infection presumably occurs when the organism is inoculated into a puncture wound caused by the contaminated claw or oral cavity of another cat.^{12,39,47} Similar to other systemic mycosis, widespread cutaneous lesions in cats likely arise from primary respiratory infection followed by hematogenous dissemination to involve skin sites.⁴⁵

Although contamination of a puncture wound by organisms in the environment is considered an important mechanism in human acquisition of the disease, human contact with cats infected with *S. schenckii* or clinically healthy cats that are exposed while living with infected cats with *S. schenckii* are now considered significant methods of zoonotic infection.^{24,36,43,56} The organism can be isolated from nail clippings of cats in households where an infection has been reported.⁴⁷ *S. schenckii* can be isolated from 100% of skin lesions, 66.2% of nasal cavities, 41.8% of oral cavities, and 39.5% of nails of cats with sporotrichosis.⁴³ In addition, 3.57% of clinically healthy cats with domiciliary contact with diseased cats had positive results from oral cultures. (See Public Health Considerations in this chapter for an additional discussion of these implications.)

After the organism enters the tissues, it converts into a yeastlike form. It can propagate locally and produce lesions at the inoculation site, it can spread up regional lymphatics and produce lymphangitis and lymphadenitis, or it can disseminate systemically in immunocompromised hosts. Many mammalian species, including dogs and cats, can become infected and develop clinical illness.

Infectious Diseases of the Dog and Cat, 3rd Edition

63.2 CLINICAL FINDINGS

Sporotrichosis has three clinical forms: cutaneous, cutaneolymphatic, and disseminated. In many instances, an animal may have more than one form simultaneously. In addition to the cutaneous manifestations, dogs and cats may have a history of lethargy and anorexia, with the physical examination revealing depression and fever, which suggests *disseminated* disease. This finding should indicate to the clinician that the animal may be immunocompromised. In general the clinical symptoms of this disease are different in dogs and cats.

63.2.1 Dogs

Sporotrichosis in dogs usually develops in the cutaneous or cutaneolymphatic form; the disseminated form of the disease is extremely rare.^{39,41} The *cutaneous* form is a multinodular condition, typically occurring on the trunk or head, with nodules in the dermal and subcutaneous layers. Nasal masses protruding from the nostrils have been observed.⁴⁹ The nodules may be ulcerated. Ulcerated nodules are associated with purulent exudate and crust formation. Dogs with the *cutaneolymphatic* form usually develop nodules on the distal aspect of one limb (Fig. 63-1). The infection then ascends proximally, following lymphatic vessels. Secondary nodules develop (referred to as *cording* of the lymphatics), which may also ulcerate and drain a purulent exudate. The cutaneolymphatic form is usually associated with regional lymphadenomegaly. Coinfection with *Cryptococcus neoformans* was reported in one dog.⁴⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 63-2 Feline sporotrichosis with multiple nodules, ulceration, and draining tracts on head. (Courtesy University of Georgia, Athens, Ga.)

63.2.2 Cats

Lesions usually occur on the distal aspects of the limbs, head, or tail-base region, sites that are commonly exposed or inoculated during cat fights. Draining puncture wounds that first appear are similar to fight-wound abscesses or cellulitis. Previous treatment with soaks and systemic antibiotics for bacterial infection results in poor or partial improvement. Subsequently, the affected areas become ulcerated, drain a purulent exudate, and form large, crusted lesions (Fig. 63-2). Extensive areas of necrosis may develop, exposing muscle and bone. The disease process may be further complicated by autoinoculation, occurring when the cat licks and scratches the lesions and then continues with normal grooming behavior, which results in multiple lesions on the extremities, face, and ears (Fig. 63-3). The involvement of the lymphatic system may not be apparent during the physical examination of affected cats. However, with necropsy or biopsy of internal organs, most cats have evidence of disseminated disease with lymph node and lymphatic vessel involvement. The lung and liver are predominant sites for gross dissemination^{44,54}; however, many other organs can be microscopically or culturally affected. *Sporothrix* organisms are commonly present and may be cultured from the blood of cats with disseminated cutaneous disease.^{43,44} Coinfection with feline immunodeficiency virus (FIV) has been documented in some of the cats with disseminated disease,⁴⁴ although a direct association has not been documented.

609

610

Infectious Diseases of the Dog and Cat, 3rd Edition

63.3 DIAGNOSIS

The initial symptoms of dogs or cats with sporotrichosis are similar to that of an animal with a deep cutaneous bacterial infection and other deep cutaneous fungal infections. The clinician should become suspicious of the possibility of sporotrichosis or other deep cutaneous fungal infections if the appropriate use of systemic antibiotics for a deep pyoderma or cellulitis results in minimal or partial improvement. Diagnosis is often suspected after cytologic or histopathologic visualization of the organism and is confirmed by cultural isolation. When bacterial cultures have been performed, the ulcerative and exudative lesions of sporotrichosis are often secondarily infected with bacterial organisms, especially *Staphylococcus intermedius*.

63.3.1 Cytology

Exudates from draining lesions should first be examined cytologically and stained for the presence of yeastlike organisms, which can be visualized by Wright (Romanowsky-type) stain and confirmed as the fungus using either culture or periodic acid–Schiff (PAS) or Gomori's methenamine silver (GMS) stains. The organism is often difficult to find in the exudates from dogs, and sporotrichosis should not be ruled out on the basis of negative cytologic findings. In contrast, *S. schenckii* is often easily identified in the exudates from cats.

However, one case report²⁰ and our own experience have indicated that the organism can be difficult to find on cytologic examination of exudates from cats and dogs. When present, *S. schenckii* appears as a pleomorphic yeast, 3 to 5 μm wide and 5 to 9 μm long, that is round, oval, or cigar-shape and may be found within macrophages and inflammatory cells or extracellularly (Fig. 63-4; see Fig. 56-5).

Infectious Diseases of the Dog and Cat, 3rd Edition

63.3.2 Fungal Isolation

When culturing for the presence of *S. schenckii*, samples of the exudate from deep within a draining tract and a piece of tissue surgically removed for a macerated tissue culture should be submitted. This approach is especially important in the dog, because usually very few organisms are present in the lesion. It is also advisable to alert the laboratory to which samples have been submitted that a diagnosis of sporotrichosis is being considered. Organisms in culture at 25° C are characterized by formation of septate hyaline hyphae, conidiophores, and conidia (Fig. 63-5). Hematogenous dissemination can be documented by blood culture of infected cats.⁴⁵

63.3.3 Histopathologic Findings

Whenever possible, the best specimens to submit for histologic examination are biopsy samples of early-forming, intact nodules. The histologic pattern observed in sporotrichosis of the dog and cat is a nodular to diffuse pyogranulomatous inflammatory reaction. It is primarily located in the dermal and subcutaneous tissues and may extend to involve the underlying skeletal muscle. As with cytologic examination, it is easier to find the organism in lesions from cats than from dogs. In the feline lesions, organisms are frequently so numerous that they are readily demonstrated within the pyogranulomatous reaction, even on sections stained with hematoxylin-eosin stain. However, experience has indicated that in cases of feline sporotrichosis the organism can occasionally be difficult to demonstrate on histopathologic examination of tissues. Because usually only a few organisms exist in canine tissues, slides should be counterstained with a fungal stain such as PAS or GMS and even then, each section of tissue should be carefully examined.

610

611

63.3.4 Immunofluorescence Testing

Specific fluorescent antibody (FA) detection of the organism (*Sporothrix* antigen-specific direct FA test) is most useful in establishing the diagnosis in dogs when the results of the just-mentioned procedures have been negative or when attempts at culturing the organism have failed.³⁹ This diagnostic procedure can be performed by the Centers for Disease Control and Prevention in Atlanta, Ga., on a sample of exudate or preferably on affected tissue from a patient suspected of having the disease (see Appendix 5). Serologic testing for antibodies to the organism is available, but a positive result indicates exposure and not necessarily active infection.

63.3.5 Genetic Detection

Molecular detection was used to identify *S. schenckii* directly in biopsy specimens from an infected cat.^{17a}

63.4 THERAPY

In the management of sporotrichosis in dogs and cats, the use of glucocorticoids or any immunosuppressive drug is contraindicated both during and after the treatment of the disease. Immunosuppressive doses of glucocorticoids have been shown to cause a recurrence of the clinical disease after it has apparently resolved.³⁹ Any concurrent bacterial infection should be simultaneously treated for 4 to 8 weeks with an appropriate antibiotic on the basis of the results of culture and susceptibility testing.³⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 63-1 Drug Therapy for Sporotrichosis^a

DRUG ^b	SPECIES	DOSE (mg/kg) ^c	ROUTE	INTERVAL (HOURS)	DURATION (MONTHS)
SSKI ^d	Dog	40	PO	8	≥2
	Cat	10–20	PO	12	
Ketoconazole ^e	Dog	5–15	PO	12	≥2
	Cat	5–10	PO	12–24	
Itraconazole capsules ^f	Dog and cat	5–10	PO	12–24	≥2
	Cat	15	PO	24	≥2
Itraconazole solution ^f	Cat	1.25–1.5	PO	24	≥2
Terbinafine ^g	Cat	30	PO	24	≥2

PO, By mouth; SSKI, supersaturated solution of potassium iodide.

- a Continue treatment at least 30 days beyond resolution of all clinical signs—usually 2 or more months of treatment.
- b See Drug Formulary, [Appendix 8](#), for additional information.
- c Dose per administration at the specified interval.
- d Supersaturated solution of potassium iodide (see Iodide, Drug Formulary, [Appendix 8](#)); treatment of choice for dogs.
- e Preferred therapy for dogs; toxicity more likely in cats on higher dosages.
- f Preferred therapy for cats; toxicity more likely in dogs on higher dosages.
- g Recommended for use in combination and only in resistant cases.⁴⁶

63.4.1 Dogs

The treatment of choice for dogs is the oral administration of a supersaturated solution of potassium iodide (SSKI) with food for 30 days beyond apparent clinical cure ([Table 63-1](#)). When sporotrichosis is not treated for an adequate time, it often recurs. Care should be taken to observe the dog for any signs of iodism (e.g., ocular and nasal discharge, dry hair coat with excessive scaling, vomiting, depression, and collapse). If iodism is observed, the medication should be discontinued for 1 week. If the side effects were mild, they may not recur, and therapy should then be reinstituted. If the side effects recur or the initial reactions were severe, an alternative treatment should be considered. Ketoconazole (KTZ) can be given to dogs that do not tolerate SSKI and to those that are refractory to iodide therapy (see [Table 63-1](#)). The authors have successfully treated a dog with sporotrichosis using KTZ at 15 mg/kg, given orally every 12 hours for 1 month beyond the apparent clinical cure (which required 3.5 months of treatment). KTZ is usually well tolerated by dogs, but potential hepatotoxicity should be monitored during therapy (see [Appendix 8](#), Drug Formulary).^{37,50} Itraconazole (ITZ) has also been shown to be a relatively safe and effective drug in the treatment of sporotrichosis in people,^{26,53,55} and was used successfully in the treatment of a case of canine sporotrichosis at 7.3 mg/kg, given orally every 12 hours with food for 5 days, then every 24 hours for 1 month beyond the apparent clinical cure (which required 3 months of treatment).⁵¹ However, hepatotoxicity was reported to occur in about 10% of dogs when ITZ was given at a dosage of 5 mg/kg twice daily and about 5% of dogs when ITZ was given at a dosage of 5 mg/kg once daily.^{22,23} This study involved the use of ITZ for the treatment of 112 dogs with blastomycosis. The subsequent recommended dosage for the use of ITZ in the treatment of blastomycosis was 5 mg/kg once daily, because this dosage minimized the adverse and toxic reactions without compromising the

Infectious Diseases of the Dog and Cat, 3rd Edition

effectiveness of the drug²³ (see [Appendix 8](#), Drug Formulary). In addition, the twice-daily dosing of ITZ has been associated with adverse cutaneous drug reactions (especially vasculitis), whereas it has not been reported to occur with the once-daily dosing regimen.^{23,29,33}

611

612

63.4.2 Cats

Treatment of sporotrichosis in the cat is more difficult than in the dog because the cat is more likely to develop toxic side effects from iodides (e.g., vomiting, anorexia, depression, twitching, hypothermia, cardiovascular failure) and KTZ (e.g., anorexia, depression, vomiting, diarrhea, fever, neurologic signs, jaundice).^{22,39} ITZ is recommended as the treatment of choice for sporotrichosis in cats (see [Table 63-1](#)). ITZ solution is preferred to the capsules because of its improved absorption and bioavailability at the recommended dosage of 1.25 to 1.5 mg/kg once daily.⁴ Because of lower bioavailability, dosage of the capsular form of the drug is 5 to 10 mg/kg once to twice daily.⁴⁴ The treatment should be continued for at least 1 month beyond the apparent clinical cure. ITZ has been shown to be effective in the treatment of systemic or disseminated sporotrichosis in people and is becoming the recommended treatment of choice.^{18,26,30,53,55} Because disseminated sporotrichosis commonly occurs in cats, the use of ITZ seems most rational. ITZ appears to be an effective alternative for the treatment of feline sporotrichosis and is better tolerated by cats than either iodides or KTZ.^{4,6,22,27,50} The potential for hepatotoxicity exists, and it is recommended that serum liver enzymes be monitored monthly during therapy. The most common side effect of ITZ in cats is anorexia; other reported side effects include vomiting, weight loss, and depression.²⁷ With concern over the development of imidazole and triazole derivative drug resistance in some deep fungal infections, terbinafine (a fungicidal allylamine) may be a useful alternative when toxicities, side effects, or a poor response to treatment develop with the use of ITZ. Terbinafine has been used as an effective treatment for feline dermatophytosis infections caused by *Microsporum canis*, with the only reported side effect being vomiting, which was alleviated by giving the medication with food.^{5,21,25} Most recently, terbinafine has been shown to be effective in the treatment of cutaneous sporotrichosis in people.^{8,17,52} Amphotericin B has only been used to treat people with life-threatening or extensive pulmonary infection.¹⁹ In a retrospective study involving 68 of 347 cats that were cured (as measured by repeated culture) with various regimens of antifungal therapy, initial treatment with ITZ and sodium iodide were most commonly used, but some of the “cured” cats were initially treated with combinations of ITZ plus fluconazole or ITZ plus terbinafine or KTZ alone.⁴⁶ Eight cats that had positive test results for FIV antibody were clinically cured. Many of the cats that were “not cured” had improved clinical conditions; however, positive fungal culture results were subsequently documented. The length of treatment for clinical resolution ranged from 16 to 80 weeks, with a mean of 36 weeks, when 41 of the cats were given two treatment regimens.

63.5 PUBLIC HEALTH CONSIDERATIONS

Traditionally, sporotrichosis has been considered to have minimal zoonotic potential. However, several reports have documented the transmission of sporotrichosis to people through contact with an infected wound or exudate from an infected cat.^{36,39,56} In recent years, hundreds of cases in people associated with cats have been reported from Brazil.^{3,44} The ready transmission of sporotrichosis from animals to people, even (although rare) in the absence of a skin-penetrating injury, appears to be a feature limited to feline sporotrichosis, presumably because of the copious numbers of organisms found in tissues, exudates, and feces of infected cats. However, inoculation of the organism may occur through the puncture wound caused by the contaminated claw or oral cavity of the

Infectious Diseases of the Dog and Cat, 3rd Edition

cat^{12,39,47} or contact with clinically healthy cats that share living space with cats infected with *S. schenckii*.⁴³ Theoretically, transmission from infected dogs seems less likely because it is often difficult to demonstrate the presence of the organism. Similarly, this infection does not spread from person to person.¹⁹

The population at greatest risk for acquiring sporotrichosis from an infected cat includes veterinarians, veterinarian assistants, and anyone exposed during treatment. An outbreak of sporotrichosis occurred in a metropolitan area among people of lower socioeconomic status who had contact with domiciled cats that roamed the neighborhood.³ In some instances, infection has occurred after nontraumatic exposure to an infected cat; one person had no known preexisting injury or penetrating wound before contracting the disease. However, inadvertent exposure to the organism may have been caused by the cat rubbing its faces against the person.

The appearance of lesions in people can be nodular, pustular, cystic, ulcerated, ulcerovegetative, or plaquelike, with or without lymphangitis. The lesions in people are frequently lymphocutaneous, localized cutaneous, mucosal (including nasopharyngeal or ocular), or widespread cutaneous lesions. Disseminated sporotrichosis is uncommon and has been observed in immunocompromised people with the acquired immunodeficiency syndrome, alcoholism, or diabetes mellitus or who are being treated with immunosuppressive therapy.¹⁴ These individuals may acquire their infection from the air or percutaneously and should not directly handle or closely associate with infected cats. Pulmonary sporotrichosis in people is difficult to treat effectively. SSKI solution has been effective in the treatment of cutaneous sporotrichosis in people. However, gastrointestinal side effects have been problematic. ITZ has been the most effective drug for treating in all forms of the disease and has had few adverse effects. In a few cases, ITZ resistance has necessitated treatment with SSKI.⁴⁰

People handling cats suspected of having sporotrichosis should wear disposable gloves. Afterward, they should remove the gloves carefully and wash their forearms, wrists, and hands with either a chlorhexidine or povidone-iodine scrub.

64 CHAPTER 64 Aspergillosis and Penicilliosis

Aspergillus and *Penicillium* are saprophytic fungi, ubiquitous in the environment, that generally cause either nasal or pulmonary and disseminated infections in dogs and cats. Everything in the environment, even pet foods, have high levels of contamination.¹² *Penicillium* spp. are often confused with *Aspergillus* spp. on gross or histologic appearance, and culture is required to distinguish the two. Cats may have gastrointestinal (GI) mucosal localization. Rarely do solitary lesions occur outside the nasal passages; nasal infections have not been suspected to disseminate to distant locations.⁶¹

Nasal infection has been associated most commonly with *Aspergillus fumigatus*. *Aspergillus* and *Penicillium* are common contaminants of body or mucosal surfaces and of the respiratory tract; therefore culture without either histologic or cytologic evidence of associated inflammation can be misleading. These organisms are generally opportunistic pathogens. Host immunocompetence is an important determinant in the development of these opportunistic fungal infections. Cell-mediated immunity (CMI) is probably the major factor in limiting systemic spread of infection.

Immunosuppressive conditions such as diabetes mellitus, persistent granulocytopenia, cytotoxic chemotherapy, glucocorticoid therapy, concurrent infection, and hereditary cell-mediated immunodeficiency are often associated with disseminated disease. German shepherd dogs are as predisposed to opportunistic infections, especially aspergillosis and hyalohyphomycosis, as they are to rickettsial diseases (see [Chapters 28 and 29](#)). For a discussion of infection with other opportunistic saprophytic fungi, see [Chapter 67](#).

64.1 CANINE NASAL ASPERGILLOSIS-PENICILLIOSIS

Kyle G. Mathews

Nick J. H. Sharp

64.1.1 Etiology

Nasal aspergillosis is encountered much more frequently than is nasal penicilliosis. The two conditions are indistinguishable other than by the microscopic appearance of their conidiophores ([Fig. 64-1](#)). *A. fumigatus* is the most common species encountered, although *Aspergillus niger*, *Aspergillus nidulans*, and *Aspergillus flavus* are occasionally involved. The species of *Penicillium* causing nasal penicilliosis have not been defined. These organisms all branch dichotomously (branches are approximately equal in diameter to the stem) at 45-degree angles and form septate, nonpigmented hyphae of approximately 3 to 8 μ m diameter in culture and in tissue specimens.⁷⁹ Both groups of fungi are ubiquitous saprophytes and are regarded as opportunistic pathogens.

64.1.2 Pathogenesis

Aspergillus is found in the environment living and growing on organic debris. Its airborne conidia of 2 to 3 μ m are released in such large numbers that they land on most inanimate and animate objects. Their small size keeps them airborne indoors and out, with most hosts inhaling hundreds of conidia daily.⁶⁰ In immunocompetent individuals, these organisms are eliminated by innate immune mechanisms. To invade the host, *Aspergillus* must adhere to and penetrate the respiratory epithelia and kill surrounding cells and resist phagocytosis.⁸¹ Conidia bind to various surface proteins; however, only a few of the existing adhesion systems, such as

Infectious Diseases of the Dog and Cat, 3rd Edition

hydrophobins, have been identified. *A. fumigatus* also produces a toxic metabolite known as gliotoxin, which inhibits macrophage phagocytosis and has a broad range of immunosuppressive actions. Other metabolites can impair mucociliary action and prolong the organism's epithelial residence. Enzymes such as proteases allow for tissue invasion.

Nasal aspergillosis is a common disease in dogs that affects primarily young to middle-aged mesaticephalic and dolichocephalic breeds. In one report of 60 dogs with nasal aspergillosis, the age of affected animals ranged from 3 months to 11 years (mean 3.3 years).⁸⁵ In contrast, nasal neoplasia tends to occur in older animals.⁵⁷ A history of nasal trauma is uncommon but has been reported in some dogs.⁵⁵ Nasal aspergillosis can occur concomitantly with, and probably secondary to, nasal tumors and nasal foreign bodies such as grass awns. Other differential diagnoses should include extension of dental disease and cleft palate, as well as lymphoplasmacytic, bacterial, and allergic rhinitis. Nasal infection with *Cryptococcus neoformans* is less common but has also been reported in dogs and should be considered as a potential differential diagnosis (see [Chapter 61](#)).⁸⁴ Dogs with disseminated aspergillosis do not generally have any clinically overt nasal involvement (see the following section).

Some dogs with nasal aspergillosis may have an underlying immunodeficiency that predisposes them to infection, and impaired lymphocyte blastogenesis responses have been reported.^{3,127} However, whether impaired CMI is a cause or a result of infection is unclear because *A. fumigatus* products have been shown to inhibit lymphocyte transformation in vitro.²³ Impaired CMI can also persist long after the organism has been eliminated.¹²⁷ In immunocompromised people receiving low-dose itraconazole (ITZ) for prevention of aspergillosis, infection developed with non-*Aspergillus* fungi that were less susceptible to the drug.⁹⁶

Invasion of bone is usually restricted to nasal turbinates; however, infection from the nasal passages can spread through the cribriform plate, palatine bone, or through the orbit, causing osteolysis. In people, invasive sinonasal aspergillosis occurs primarily in immunocompromised hosts. Mucosal invasion is followed by infarction and necrosis and spread of infection in a centrifugal fashion to adjacent mucosae and bone.¹³⁸

Pulmonary aspergillosis is the primary form of localized disease observed in people. The long nasal passages of dogs may more effectively trap *Aspergillus* spores before they reach the lower airways. Pulmonary aspergillosis caused by *A. niger* was documented in a dog.⁷⁴

64.1.3

Clinical Findings

Clinical and historical signs consistent with nasal aspergillosis in dogs include mucopurulent nasal discharge, sneezing, signs of nasal discomfort (pawing at the face or pain on palpation), epistaxis, decreased appetite, lethargy, and nasal planum depigmentation or ulceration ([Fig. 64-2](#)). Stertor, stridor, open-mouth breathing, or any combination may also be noted. Nasal discharge is initially unilateral in most cases but often progresses to bilateral involvement caused by destruction of the midline nasal septum. *A. fumigatus* has been shown to produce an endotoxin that is both hemolytic and dermonecrotic.¹⁴³ This toxin presumably causes the turbinate necrosis and erosion of the rhinarium, which occur in infected animals. With time, paranasal extension may result in facial swelling; nasolacrimal duct obstruction or destruction may result in epiphora. Orbital invasion can result in oculonasal discharge, exophthalmos, discomfort on opening the mouth, corneal injury, or strabismus. Enophthalmos and phthisis bulbi may be found in the healing stages.¹⁶⁰ Erosion of the cribriform plate, if it occurs, usually does not result in clinical signs but may preclude topical therapy. On rare occasions, with fulminant invasive fungal rhinitis or sinusitis, an animal will show signs of intracranial disease that are

613

614

Infectious Diseases of the Dog and Cat, 3rd Edition

caused by extension of nasal or frontal sinus infection.¹⁰⁰ In other animals, with more long-standing and less virulent nasal fungal infections, arthrolithiasis or pastelike exudates may develop within the nasal passages or sinuses as a result of caseous sinusitis caused by the organism.⁹⁴ With this mycetoma formation, radiographic studies may show sinus opacification often with flocculent calcification. Mucopurulent, cheesy or claylike material is often found by surgical or endoscopic examination. Histopathologic changes are a dense conglomeration of hyphae separate from but adjacent to mucosa of the sinus. The mucosa itself has chronic suppurative inflammation without fungal invasion.

Fig 64-1 *Aspergillus* spp. (right) Septate hyphae (2 to 8 μ m) give rise to unbranched conidiophores. Each conidiophore has a rounded tip (vesicle) covered with flask shaped phialides, which support chains of round conidia. *Penicillium* spp. (left) Septate hyphae (2 to 5 μ m) give rise to branched or unbranched conidiophores with secondary branches. Secondary branching gives *Penicillium* its brushlike appearance. Flask-shaped phialides support chains of round conidia.

Signs of pulmonary aspergillosis include fever, cough, and mucopurulent nasal discharge. See disseminated infection later in this chapter for other signs should systemic spread develop.

64.1.4 Diagnosis

Physical examination should include facial palpation for evidence of pain or asymmetry, evaluation of airflow through each nostril, and an oral examination. Established guidelines used to make a definitive diagnosis, include positive results on biopsy, a positive titer with positive culture results, or a positive titer with radiographic or computed tomography (CT) scan changes suggestive of fungal rhinitis (turbinate loss).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 64-2 Ulceration of the external nares in association with *A. fumigatus* infection. (Courtesy Kyle Mathews, North Carolina State University, Raleigh, N.C.)

64.1.4.1 Organism Cultivation

Aspergillus spp. can be isolated from cultures of the nasal passages as a result of colonization of the immunocompetent host. Unfortunately, confirmation of the diagnosis usually requires multiple independent tests because *Aspergillus* spp. are often part of the endogenous flora in the nasal cavity of many animals, and culture alone is unreliable and misleading (Fig. 64-3).⁵⁶ Culture should be performed from biopsy specimens of healthy and diseased nasal and sinus mucosae and bone adjacent to areas of necrosis. Paired specimens should also be evaluated for histopathology. Laboratory culture is also needed to differentiate *Aspergillus* or *Penicillium* infections from other saprophytic infections, such as those caused by *Mucorales* or *Alternaria* spp. In addition, fungal culture results may also be negatively affected by secondary bacterial overgrowth. *Pseudomonas* spp. and Enterobacteriaceae cause common secondary infections of necrotic tissue within the nasal chamber.

64.1.4.2 Serologic Testing

Numerous techniques for determination of *Aspergillus* serum fungal-specific antibody titers have been evaluated, including agar gel double diffusion (AGDD), counter-immunoelectrophoresis (CIE), and enzyme-linked immunosorbent assay (ELISA) techniques. AGDD and CIE tests have been reported to be highly sensitive and specific, while ELISA appears to be less reliable.^{73,77,110} However, negative AGDD results should be viewed with some skepticism if the clinical, radiographic, and rhinoscopic picture is consistent with fungal rhinitis. Earlier studies using this method had low false-negative results, but multiple *Aspergillus* antigens preparations were used. Current AGDD tests typically use only one antigen, and their accuracy has not been well documented. We (KGM and NJHS) have obtained several false negative results using AGDD (Meridian Diagnostics, Inc., Fungal immunodiffusion system, Cincinnati, Ohio) early in the disease process from histologically confirmed cases of nasal aspergillosis. Many of these cases had positive titer results when retested at a later date. Furthermore, nasal *Penicillium* infection, which is clinically

Infectious Diseases of the Dog and Cat, 3rd Edition

indistinguishable from aspergillosis, can result in a negative AGDD test result if only *Aspergillus* antigens

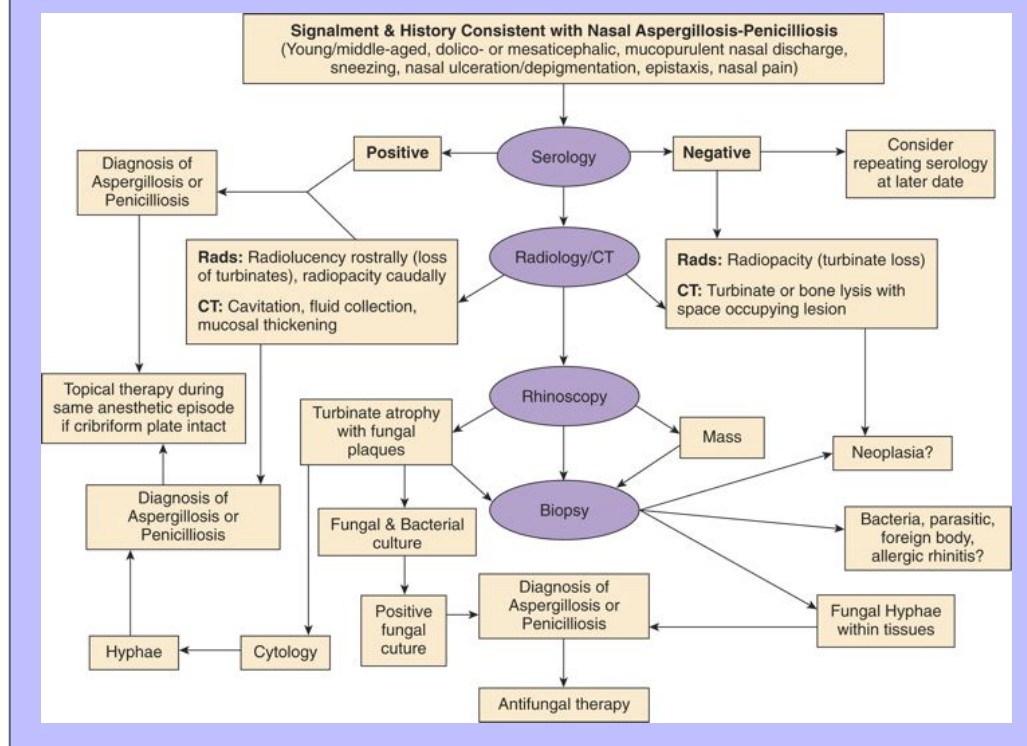

614

are used.⁵⁶ In addition, a positive result does not eliminate the possibility of a concurrent disease process

615

such as neoplasia. Request for an *Aspergillus* titer, followed by general anesthesia, a radiographic evaluation, and rhinoscopy with the intent to perform biopsy and culture, is a logical diagnostic approach (see Fig. 64-3).

Fig 64-3 Decision-making algorithm for the diagnostic evaluation of dogs with clinical signs consistent with nasal aspergillosis-penicilliosis.

64.1.4.3 Antigen or Genetic Detection

See these topics later in this chapter under Disseminated Aspergillosis in Dogs.

64.1.4.4 Radiographic Imaging

Nasal and frontal sinus radiographs can be used as a screening tool to evaluate dogs with suspected fungal rhinitis. Rostral radiolucency (cavitary destruction) caused by turbinate lysis or a mixed pattern of caudal lucency and opacity (or both) are usually seen on dorsoventral views, while increased radio opacity and frontal bone thickening on rostrocaudal “skyline” views are typical.¹³⁹ Nonspecific thickening of the mucosa of the inner surface of bones of the frontal sinus, maxillary recess, and nasal cavity is often noted.¹¹⁹ Changes may be asymmetrical because the disease may affect one nasal cavity initially and then spread to the opposite side. The CT and magnetic resonance imaging (MRI) anatomy of the mesaticephalic canine nasal cavity has been well described.^{36,48} Studies have shown that CT is superior to radiography for defining

Infectious Diseases of the Dog and Cat, 3rd Edition

the extent of nasal disease, detection of cortical bone lesions, and in differentiating infectious from neoplastic rhinitis.^{25,99} MRI was helpful in differentiating between a thickened mucosa and secretions or fungal colonies.^{116a} Nasal neoplasia results in loss of turbinates and bone, but these structures are replaced by a soft-tissue density (mass). Fungal rhinitis is typified by loss of turbinates with resultant air-filled cavities and mucosal thickening resulting from edema and inflammation (Fig. 64-4).^{118,119} In some cases of nasal aspergillosis, even CT images may be difficult to interpret because significant accumulations of fluid may occur and obscure fungal granulomas, concomitant masses, or turbinate and frontal sinus detail. CT or MRI is required to evaluate the integrity of the cribriform plate.

64.1.4.5 Response to Empirical Therapy

Topical treatment may be performed without advanced imaging techniques if nasal radiographs and other diagnostic tests are suggestive of fungal infection. However, if evidence of caudal nasal involvement exists, referral for CT is recommended. This course of action is recommended because erosion of the cribriform plate may contraindicate the use of topical infusions. Although complications arising from leakage of antifungal medications into the central nervous system (CNS) of dogs with fungal rhinitis have not been well described, neurologic complications resulting in euthanasia following topical therapy have been reported in two animals with suspected cribriform damage.⁸⁵ Owners of affected dogs should be informed of this concern before attempting topical therapy with large volumes of antifungal medication infused under pressure. If cribriform involvement is detected on CT, dogs may be treated with oral ITZ.

Cavitation caused by turbinate destruction (*), fluid accumulation (*arrow*), fungal granuloma. (Courtesy Kyle Mathews, North Carolina State University, Raleigh, N.C.)

64.1.4.6 Endoscopic Evaluation

Following radiographic or CT evaluation of the nasal cavity, rhinoscopy should be performed, preferably during the same anesthetic episode.⁸⁸ Nasal examination is never performed before radiographic procedures because hemorrhage induced by rhinoscopy will alter the results. A sterile rigid endoscope is commonly used

Infectious Diseases of the Dog and Cat, 3rd Edition

for rhinoscopy. Evaluation of a lateral frontal sinus can also be performed with a rigid endoscope after penetrating the dorsal wall of the sinus with a Steinman pin. A flexible bronchoscope has the added advantage of allowing visualization of the nasopharynx by retroflexion of the bronchoscope around the soft palate.

After inserting the endoscope through the rostral nares, it is first directed into the ventral nasal meatus toward the nasopharynx. It is then directed into the dorsal nasal meatus toward the olfactory epithelium, the openings (ostia) of the frontal sinuses, and the cribriform plate. If dorsal examination were performed first, hemorrhage may potentially result in an inability to explore the ventral nasal cavity thoroughly. The advantages of direct visualization of the nasal cavity include a more thorough understanding of the nature of the disease process and the potential to place a biopsy instrument at the area of interest. Many endoscopes are equipped with biopsy ports or sleeves that simplify tissue sampling. In addition, a biopsy instrument may be inserted alongside the endoscope if space permits. Additionally, a cuffed endotracheal tube is required, as is packing the pharynx with laparotomy sponges to prevent aspiration of blood, flush, and nasal secretions.

Biopsy specimens are placed in 10% buffered formalin for histologic examination, in appropriate media for bacterial and fungal cultures, and are also rolled onto glass slides for immediate cytologic examination (Fig. 64-5). Following resolution of hemorrhage and before recovery from anesthesia, pharyngeal sponges are removed, and the pharynx is suctioned.

Rhinoscopic evaluation of dogs with aspergillosis typically reveals areas of turbinate atrophy, mucopurulent discharge, and fungal plaques. Fungal plaques may be white, off-white, or have a greenish tint. The surface of a plaque may be fuzzy in appearance resulting from the presence of conidiophores (fruiting bodies) (Fig. 64-6, A and B). Collections of exudate should not be mistaken for plaques.

If a diagnosis of nasal aspergillosis is rendered following nasal examination based on consistent radiographic or CT findings and the presence of fungal plaques or hyphae, or both, on cytologic examination, topical treatment may be performed during the same anesthetic episode.

Fig 64-5 Nasal cytologic specimen collected during rhinoscopic evaluation of a dog nasal aspergillosis. Note septate hyphae (*arrows*). (Courtesy Eleanor Hawkins, North Carolina State University, Raleigh, N.C.)

Infectious Diseases of the Dog and Cat, 3rd Edition

64.1.5 Pathologic Findings

Biopsy of suspicious lesions is required to demonstrate mucosal invasion. Histopathologic abnormalities of tissue biopsy specimens are erosions and ulcerations of respiratory epithelium, submucosal infiltrates with lymphocytes, plasma cells and neutrophils, and a neutrophilic exudate surrounding large mats of branching septate fungal hyphae. The hyphae have terminal bulbs with swellings consistent with *Aspergillus* spp.

64.1.6 Therapy

64.1.6.1 Systemic Therapy

Treatment of nasal aspergillosis with systemic antifungal medications such as thiabendazole, ketoconazole (KTZ), and fluconazole has been disappointing in that the reported successful response rate is only 43% to 60%.¹ Response to oral administration of ITZ has been approximated at 60% to 70%,⁸³ but currently, no large studies evaluating systemic treatment with ITZ have been done, and cost of the drug is often prohibitive. Hepatic toxicosis may mandate temporary or permanent discontinuation of ITZ in 5% to 10% of dogs, and serial monitoring of serum alanine aminotransferase (ALT) concentration is recommended.⁸³ Fluconazole at oral doses of 2.5 to 5.0 mg/kg was effective for treatment of canine nasal aspergillosis; however, the success was lower than that using topical enilconazole.¹²⁵

616

617

Fig 64-6 **A**, Endoscopic appearance of a fungal granuloma from within the nasal passage near the connection with the frontal sinus. Loss of turbinate bone is apparent, and the mass is golden-brown in color. Some of the surface is white and fuzzy in appearance caused by the presence of *Aspergillus* conidiophores. **B**, Similar fungal granuloma within the lateral frontal sinus of Rottweiler with nasal aspergillosis, as viewed by surgical sinusotomy and rhinostomy. (**A** courtesy Christiane Stengel, University of Georgia, Athens, Ga.; **B** courtesy Kyle Mathews, North Carolina State University, Raleigh, N.C.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Systemic therapy is indicated as part of the treatment regimen if the fungus has invaded extranasal structures. For dosages of recommended antifungal drugs, see [Table 64-1](#). The results obtained for systemic therapy are not as good as those obtained for topical agents. Systemic antifungal therapy can be associated with side effects of hepatotoxicity or cutaneous eruptions.

Amphotericin B (AMB) has been used in the past to treat nasal aspergillosis in dogs.^{5,134} The results were generally unsuccessful, and it is not recommended. Given that AMB has some efficacy against pulmonary disseminated infections in people and disseminated infections in dogs (see later discussion), the problem likely relates to insufficient concentrations in the nasal passages by systemic administration. Terbinafine, an antifungal drug used to treat disseminated aspergillosis in people, has been tried on an empirical basis, alone and combination with azole drugs, to treat refractory cases of nasal aspergillosis. Further studies are needed to determine the efficacy of this drug in nasal aspergillosis.

64.1.6.2

Topical Therapy

Topical administration of enilconazole and clotrimazole is more effective compared with orally administered antifungal medications.² Intranasal administration of enilconazole requires a sinusotomy to place indwelling catheters into the nasal cavity or frontal sinuses, or both.^{127,131} However, intrasinus administration of enilconazole was described using endoscopically placed catheters passed into the frontal sinuses and nasal passages.¹⁶³ After catheter placement, 5 to 10 ml (50 mg/ml = 10 mg/kg) of enilconazole are administered twice daily for 1 to 2 weeks. Larger volumes are avoided because of risk of aspiration. Nasal discharge resolved in 19 (80%) of 24 dogs treated solely with topical administration of enilconazole.¹³¹ Common complications include premature removal of catheters, transient postoperative subcutaneous emphysema, inappetence, and ptyalism.^{127,130,131} As previously noted, erosion of the cribriform plate may be a contraindication to infusion of large volumes of topical medications under pressure. However, one of the authors (NS) has treated two dogs with small volumes of enilconazole, as noted here, without adverse effect.

A 1-hour infusion of clotrimazole, administered to anesthetized dogs, resulted in the resolution of clinical signs in many cases.^{13,29,85} Topical administration of clotrimazole causes direct damage to fungal membranes and inhibits fungal ergosterol synthesis.⁶³ Although a surgical procedure (sinusotomy) was used for catheter placement into the frontal sinuses, many cases resolved after a single treatment.²⁷ In addition, the complications associated with indwelling catheters were eliminated, and hospitalization times were substantially reduced.

In a study evaluating the distribution of dye injected into cadaver skulls of normal dogs, a noninvasive technique for intranasal infusion resulted in better distribution of infusate within the nasal cavity and paranasal sinuses than did techniques that used catheters placed via sinusotomy ([Fig. 64-7](#)).¹⁰⁹ Large volumes of infusate may be administered and leakage minimal because the nares and nasopharynx were occluded during intranasal infusion. With cadaver skulls placed in dorsal recumbency, bilateral administration of 50 ml (100 ml total) through the nares resulted in excellent distribution of infusate to the entire nasal cavity and frontal sinuses with minimal leakage into the pharynx.¹⁰⁹ This noninvasive intranasal technique resulted in good distribution of infusate to the nasal cavity and frontal sinuses, as determined by evaluation of pre- and postinfusion images on CT scans, in 12 dogs with confirmed fungal rhinitis.⁸⁶ The

Infectious Diseases of the Dog and Cat, 3rd Edition

percentage of the lateral sinus filled with infusate varied from 10% (enough to cover the roof of the lateral sinus) to 100% (mean, 42%). The infusate that mixed with present exudates, as outlined previously, obscured fungal granulomas.⁸⁶

One study evaluated 60 dogs with nasal aspergillosis treated with 1-hour infusions of clotrimazole.⁸⁵ The goals of the study were to examine the clinical response to topical administration of clotrimazole in dogs

617

with nasal aspergillosis and to compare the efficacy of surgical versus nonsurgical placement of catheters.

618

Topical 1% clotrimazole solution was infused during a 1-hour period via surgically placed frontal sinus and nasal catheters (27 dogs) and via nonsurgically placed intranasal catheters (18 dogs). An additional 15 dogs required and received two to four infusions by either route. Topical administration of clotrimazole resulted in resolution of clinical disease in 65% of dogs after one treatment and in 87% of dogs after one or more treatments. No difference in outcome was noted between surgically and nonsurgically placed catheters.

Table 64-1 Therapy for Nasal Aspergillosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION
Amphotericin B (deoxycholate)	D	0.25	IV	48	^c
Itraconazole	B	5	PO	12	prn ^d
Fluconazole	D	2.5–5.0	PO	24	prn ^d
Amphotericin B lipid complex	D	2–3	IV	3 days per week	^e
	C	1	IV	3 days per week	^f
Terbinafine	D	5	PO	12	prn ^g

D, Dog; B, dog and cat; C, cat; PO, by mouth; IV, intravenous; prn, as needed.

- a For additional information, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c Until a cumulative dose of 4 to 8 mg/kg is reached for cats and 8 to 12 mg/kg for dogs.
- d Therapy to control infection may require months to years, although clinical remissions may be achieved; the infection may reactivate in a variable time period after discontinuing treatment. Topical therapy with azole drugs is generally superior to systemic administration for nasal aspergillosis; see text and reference 119a.
- e For a total of 9 to 12 treatments until a cumulative dose of 24 to 27 mg/kg is reached.
- f For a total of 12 treatments until a cumulative dose of 12 mg/kg is reached.
- g This dose is extrapolated from human studies. No efficacy studies have been conducted on this drug for treatment of aspergillosis in dogs or cats; however, it has been used empirically in nonresponsive cases.

Topical administration of clotrimazole, using either technique, is therefore an effective treatment for nasal aspergillosis in dogs. The use of noninvasive intranasal infusion of clotrimazole eliminates the need for surgical trephination of the frontal sinuses in many dogs and is associated with fewer complications.^{13,85,133} The most common posttreatment complication in dogs treated by trephination of the frontal sinuses was subcutaneous emphysema. Subcutaneous and retrobulbar leakage and nasolacrimal duct filling of clotrimazole have also occurred with no apparent adverse effects. Nasal discharge ceases in most dogs by 2 weeks after topical clotrimazole therapy.⁸⁵ A repeat treatment is recommended if nasal discharge continues

Infectious Diseases of the Dog and Cat, 3rd Edition

without improvement 2 weeks after the initial treatment. Sequential evaluation of *Aspergillus* titers does not aid in the decision to re-treat because titers may remain elevated for years despite resolution of disease.^{126,127}

The volume of the nasal cavity and frontal sinuses varies depending on the size of the dog, the extent of turbinate destruction, and the volume of accumulated exudate. Based on a study in cadavers, the average volume of the frontal sinuses in breeds predisposed to fungal rhinitis was 25 ml per side.¹⁰⁹ The nasal cavity and sinuses can be flooded with a larger volume of infusate (50 to 60 ml per side), resulting in distribution of the infusate to all areas of the nasal cavity and frontal sinuses. A 1% formulation of clotrimazole in a polyethylene glycol base (Lotrimin® solution, Schering Corporation, Kenilworth, N.J.) is readily available in a 30-ml vial, which makes treatment with two vials per side convenient. Sixty ml per side is used in mid-sized to large breed dogs, regardless of head size. Thirty ml per side should be adequate for smaller breeds. Formulations that contain polyethylene glycol, isopropyl alcohol, and propylene glycol (Canesten® solution, Miles Canada, Etobicoke, Ontario, Canada) should be used with caution because they may result in pharyngeal irritation and edema.^{19,28}

Preliminary information on the use of enilconazole (Imaverol, Janssen-Cilag SA, Beerse, Belgium) administered in a similar fashion was not favorable. Of four dogs treated in this manner, one resolved after two treatments, one died from sepsis after the second treatment, and two developed profuse fungal growth in the face of therapy.¹⁰ In a group of 10 dogs treated with a 1-hour Imaverol infusion, five were cured and five failed treatment.⁵⁹ In both cases, fairly high concentrations of enilconazole were given (5% to 10%). These concentrations are probably much higher than necessary to kill the fungus, and the carrier detergent may result in irritation of the nasal mucosa if left in place for 1 hour.¹⁰ Subsequent studies using 1% Imaverol as a 1-hour soak have reported more favorable results.^{117,163} Twenty of 36 dogs (56%) were cured after a single treatment, and 34 of 35 (94%) were cured after one to three treatments.¹¹⁷ Enilconazole is available for poultry in the United States as Clinafarm-EC (Sterwin Labs, Inc., Millsboro, Del.). Clinafarm-EC contains alcohol and therefore should be used with some caution until more information is available. Clinifarm-EC (5%) has been used as a 1-hour infusion.⁸⁹ In this study, the drug was administered to six anesthetized dogs after endoscopic placement of catheters in the caudal portion of the nasal cavity and frontal sinuses.⁸⁹ The dogs received two to three treatments, with 50 to 200 ml infused during each treatment. All six dogs showed favorable clinical response soon after treatment. Two dogs were treated with ITZ concurrently. Three dogs that were followed for a mean of 16.5 months had marked clinical improvement. Using similar endoscopic placement of infusion catheters, 2% enilconazole (Imaverol) infused over 1 hour resulted in cure in all six dogs in one report.¹⁶³ Three of the six dogs were treated simultaneously with oral KTZ.

A 1-hour infusion with 1% clotrimazole or enilconazole (Imaverol) should now be considered the treatment of choice for nasal aspergillosis-penicilliosis when the cribriform plate is intact. If the cribriform plate is damaged, then systemically active drugs should be given. Re-treatment with infusions should be performed if nasal discharge does not cease within 2 weeks. In one study, clotrimazole was infused directly in the frontal sinuses via trephine holes.⁴⁴ Whether an advantage to using enilconazole exists for the second treatment if the first was with clotrimazole, and vice versa, is unclear. The decision to treat via intranasal infusion with the patient in dorsal recumbency versus sinusotomy with the patient in sternal recumbency should be based on the presence or absence of fungal granulomas within the frontal sinuses. We (KGM and NJHS) have seen several cases fail with topical clotrimazole therapy when a large granuloma was evident within a frontal sinus. Clinical signs typically improve but do not completely resolve. Our assumption is that penetration of the drug into the center of the granuloma is inadequate and results in regrowth. Following

618

619

Infectious Diseases of the Dog and Cat, 3rd Edition

sinusotomy, curettage, lavage, and suction to remove large fungal balls, topical treatment via the sinusotomy is usually effective.

Fig 64-7 **A**, Catheter position with the dog in dorsal recumbency. A Foley catheter with the balloon inflated in the nasopharynx and pharyngeal gauze sponges (not shown) minimize leakage of infusate caudally. A cuffed endotracheal tube (*et*) further diminishes the risk of aspiration. Sixty-milliliter syringes are used to inject infusate into the dorsal nasal meatus via polypropylene infusion catheters. Inflated Foley catheter balloons obstruct the nares to diminish leakage of infusate rostrally. Tubing clamps on Foley catheters are closed when fluid is observed within the catheter lumen. **B**, Sagittal section showing the position of the endotracheal tube (*et*), nasopharyngeal Foley catheter (*nptf*), pharyngeal sponges (*s*), infusion catheter (*ic*), and rostral nasal Foley catheter (*nf*) in relation to the hard palate (*hp*), soft palate (*sp*), cribriform plate (*cp*), rostral frontal sinus (*rfs*), medial frontal sinus (*mfs*), and lateral frontal sinus (*lfs*). (From Mathews KG et al. 1996. Computed tomographic assessment of noninvasive intranasal infusions in dogs with fungal rhinitis, *Vet Surg* 25:309–319, 1996. Reprinted with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

In the few cases in which 1-hour topical infusions of 1% clotrimazole or enilconazole (Imaverol) fail, the placement of indwelling tubes for instillation of enilconazole over 1 to 2 weeks (as previously noted) might be considered as a salvage treatment.

Topical therapy will often fail when the organism invades soft-tissue structures outside of the nasal cavity. These cases require a combination of topical therapy (assuming the cribriform plate is intact) with a systemically active agent such as ITZ.^{85,113,131}

Open nasal cavity treatment of nasal aspergillosis with povidone-iodine solution has been reported but is used only for cases that fail less aggressive treatment options.^{93,104} We have had to resort to this method in one animal which failed to resolve following sinusotomy and multiple treatments with both enilconazole and clotrimazole. Resolution of nasal aspergillosis (mixed infection with *A. fumigatus* and *A. niger*) in this case required a combination of open nasal cavity treatment with simultaneous oral administration of ITZ (Fig. 64-8).

* References: 13, 29, 83, 85, 119a, 127, 130, 131, 133, 160, 163.

64.1.6.3 Surgery

Rhinotomy or sinusotomy and turbinectomy have no roles in the treatment of fungal rhinitis other than to remove fungal granulomas, fungus balls, or mycetomas. The tendency to continue with a turbinectomy should be strongly resisted. Turbinectomy is of no benefit in controlling the nasal discharges and is often detrimental.³ Care must be taken to cause as little damage as possible to nasal and turbinate mucosa and to the nasofrontal ostia.^{86,149}

* References: 54, 78, 131, 152, 153.

64.1.7 Prognosis

The best indication of successful therapy is the rapid resolution of nasal discharge or epistaxis, pain, and ulcerated nares. In some dogs, a mild serous to mucopurulent, crusty discharge may persist at one or both nostrils, presumably as a result of the reorganized nasal architecture. In evaluation of CT abnormalities, no correlation was found between the severity of changes on CT with the response to intranasal infusion of enilconazole; however, dogs with the least abnormalities had the best clinical response to one infusion.¹¹⁷ Serology is of only limited value in assessing the response to treatment. Although titers tend to decline within 1 to 2 years of successful therapy, this occurrence is not a reliable indicator. Positive titer results may persist for more than 2 years using ELISA methodology or for 5 years using agar gel immunodiffusion (AGID) in dogs that remain free of disease.¹²⁷

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 64-8 Open nasal cavity treatment of a dog with recurrent nasal aspergillosis.
(Courtesy Kyle Mathews, North Carolina State University, Raleigh, N.C.)

Relapse of fungal disease does not appear to be a common problem with canine nasal aspergillosis-penicilliosis once the clinical signs of infection have been eliminated. Of 43 dogs that had shown complete resolution of clinical signs after treatment with a variety of systemic and topical antifungal drugs, only one suffered a relapse of fungal rhinitis during followup periods, ranging from 6 months to 5.5 years.¹²⁷ Similarly, recurrent fungal rhinitis was documented in only 1 of 60 dogs following clotrimazole treatment.⁸⁵ A bacterial rhinitis may develop in up to 12% to 25% of dogs after successful resolution of the primary fungal disease, possibly because of previous destruction of the nasal anatomy by the fungus. Bacterial rhinitis is characterized by a return of the profuse mucopurulent nasal discharge but usually without epistaxis or facial pain. Fungal plaques are absent in these dogs, and the discharge responds to antibiotic therapy based on culture and antimicrobial susceptibility results.^{78,85,131,152}

64.1.8 Public Health Considerations

No instances of infection in people arising from dogs or cats have been documented. Infection in all species occurs from common environmental sources. A prudent course of action, however, for the clinician is to inform an owner that immunosuppressed individuals should not be exposed to affected animals that may be discharging large quantities of fungal hyphae and spores.

64.2 FELINE NASAL ASPERGILLOSIS-PENICILLIOSIS

Kyle G. Mathews

Kamil Tomsa

Infectious Diseases of the Dog and Cat, 3rd Edition

Although rarely reported, both *Aspergillus* and *Penicillium* spp. have been incriminated in sinonasal infections in cats (Table 64-2). Systemic immunosuppression is not critical to the development of nasal or paranasal aspergillosis.^{2,123} Only one of seven reported cats with nasal aspergillosis was feline leukemia virus (FeLV) positive.⁴⁹ Clinical signs have included chronic mucopurulent nasal discharge, epistaxis, and mandibular lymphadenomegaly. In several cases, the infection appeared to begin in, or then extended into, the extranasal or orbital tissues, causing exophthalmos.^{51,52,105,157} The clinical symptoms are usually localized to one side of the nasal-paranasal-orbital cavities, but the disease can be bilateral. Nasal aspergillosis-penicilliosis is clinically indistinguishable from chronic viral rhinitis and nasal-paranasal neoplasia, and, as in these conditions, secondary bacterial infection is common. Bone erosion and focal soft-tissue opacities are typical but are nonspecific diagnostic imaging findings in all the previously listed clinical entities. Chronic viral rhinitis in cats is usually bilateral and does not cause loss of teeth, as does nasal neoplasia.⁹⁷

Identification of irregular mineralized densities in the nasal-paranasal cavities should raise the suspicion of *Aspergillus* infection (Fig. 64-9, A and B).^{94,144} Rhinoscopic findings were reported in three affected cats and included diffuse reddening of nasal mucosa, copious white-grey discharge, profound loss of turbinates, and the presence of a white-yellow mass.¹⁴⁴ The diagnosis of feline nasal aspergillosis-penicilliosis should be based on typical clinical and diagnostic imaging findings accompanied by histologic evidence of pyogranulomatous fungal rhinitis, with variable degrees of tissue invasion and necrosis. Fungal culture should be best attempted on samples taken directly from fungal colonies within the respiratory passages. However, culture was successful in only two of seven reported cases.^{52,105} Presence of serum anti-*Aspergillus* antibodies in affected cats has been documented by AGID test⁴⁹ and serum immunoelectrophoresis¹⁴⁴ and may be considered useful noninvasive diagnostic information. Further studies may be needed to determine the prevalence of these antibodies in clinically healthy cats and those with other non-*Aspergillus* nasal disorders.

Currently, only limited information is available regarding the best therapeutic approach. Systemic therapy with ITZ was attempted in two animals. One cat with extranasal involvement had progressive worsening of clinical signs and was euthanized despite treatment with ITZ, topical clotrimazole, and surgery.⁵² Another animal with disease confined to the nasal-paranasal cavity had to have ITZ therapy stopped after 6 weeks because of hepatotoxicity.¹⁴⁴ Clinical signs recurred in this cat, but they abated following a single treatment with intranasal clotrimazole. Treatment with noninvasive 1-hour infusion of topical clotrimazole, combined with systemic therapy, if extranasal involvement is present, is a reasonable approach until more information is available. ITZ is preferable to KTZ for systemic therapy in cats and should be given at a dosage of 10 mg/kg once daily.^{83,91} Sinusotomy may be a final resort to remove fungal balls or mycetomas and provide drainage.^{49,162} The prognosis for a resolution of clinical illness and fungal infection in feline sinonasal aspergillosis is generally poor.

64.3 CANINE DISSEMINATED ASPERGILLOSIS

Michael J. Day

64.3.1 Etiology and Pathogenesis

Most cases of canine disseminated aspergillosis have occurred in German shepherd dogs (age range, 2 to 8 years) and have been reported from Australia^{31,72,154} and California.^{31,66} The disease has also been documented in Spain,^{101,106} Belgium,²⁴ the United Kingdom,¹⁵ South Africa,⁸ and the eastern United

620

623

Infectious Diseases of the Dog and Cat, 3rd Edition

States.^{15,26,47,70} Canine disseminated aspergillosis is probably more ubiquitous than the reports suggest. In cases in which the species has been identified, infection has involved, in decreasing frequency, *Aspergillus terreus*, *Aspergillus deflexus*, *Aspergillus flavipes*, and *A. fumigatus*. This finding contrasts with nasal aspergillosis (see previous discussion on Nasal Aspergillosis) in which *A. fumigatus* is most common. The portal of entry of *Aspergillus* is thought to be via the respiratory tract with subsequent hematogenous spread. Rare cases of infection restricted to the lungs are recorded.⁴⁵ As with any blood-borne pathogen, common sites of embolic dissemination of fungal organisms are the intervertebral disks, renal glomeruli, and uveal tracts. Other parenchymatous organs or muscles and long bones may be affected.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 64-2 Summary of Cases of Feline Nasal Aspergillosis-Penicilliosis

SIGNALMENT HISTORY ^a	DIAGNOSIS	IMMUNOLOGY (I) CULTURE (C)	HISTOPATHOLOGY	RADIOGRAPHY	TREATMENT (T) OUTCOME (O)
6.5 yr, F, DSH, exophthalmos ¹⁰⁵	Bilateral sinonasal penicilliosis with orbital extension and fungal pneumonitis	I: None C: <i>Penicillium</i> spp.	Inflammation with necrosis and fungal hyphae	Increased opacity of sinuses, zygomatic lysis	T: None O: Euthanized
4 yr, M, DLH, exophthalmos ¹⁵⁷	Bilateral orbital aspergillosis with extension into frontal sinuses	I: None C: <i>Aspergillus</i> spp., <i>Pasteurella</i>	Inflammation with necrosis and fungal hyphae		T: None O: Euthanized
4 yr, M, DSH with previous viral URI, unilateral nasal discharge ⁴⁹	Right sided sinonasal aspergillosis	I: AGID positive for <i>A. fumigatus</i> ; FeLV-positive C: Negative for fungus; heavy growth of hemolytic streptococci		Turbinate loss/nasal radiolucency, increased frontal sinus opacity	T: Rhinotomy O: Slow improvement, resolved 3 mos postoperatively
8 yr, M, Persian with epiphora, nasal discharge, exophthalmos ⁵²	Unilateral orbital, bilateral sinonasal, and nasopharyngeal aspergillosis	I: None C: <i>Aspergillus</i> spp., <i>Staphylococcus</i> spp.	Inflammation with fungal hyphae – morphology consistent with <i>Aspergillus</i> spp.	CT: soft-tissue mass effect in left orbit, and dorsal to soft palate; increased nasal and frontal sinus opacity	T: ITZ, sinusotomy, orbitotomy, topical clotrimazole O: Orbital involvement progressed requiring exenteration; euthanized 4 mos later for difficulty swallowing
2 yr, FS, Siamese with unilateral nasal discharge ¹⁴⁴	Unilateral nasal aspergillosis	I: IEP positive for <i>A. fumigatus</i> C: Negative for fungus; <i>Pasteurella dagmatis</i> , α -hemolytic <i>Streptococcus</i> spp.	Inflammation with fungal hyphae		T: None O: Resolved spontaneously
12 yr, MN, Persian with bilateral nasal discharge, epiphora, epistaxis, sneezing ¹⁴⁴	<i>Aspergillus</i> or <i>Penicillium</i> fungal rhinitis with anterior uveitis	I: FeLV, FIV, coronavirus negative; IEP negative for <i>A. fumigatus</i> C: Negative for fungus; <i>Escherichia coli</i>	Inflammation with necrosis, calcification, and fungal hyphae	CT: unilateral turbinate loss with nasal object of similar density to teeth	T: None O: Euthanized

Infectious Diseases of the Dog and Cat, 3rd Edition

8 yr, MN, Persian with chronic unilateral nasal discharge ¹⁴⁴	Unilateral sinonasal aspergillosis	I: IEP positive for <i>A. fumigatus</i> C: Negative for fungus and bacteria	Frontal sinus inflammation with fungal hyphae, nasal inflammation	CT: unilateral turbinate loss, fluid in sinuses, vomer deviation, orbital bone thinning	T: 6 wks ITZ, followed by topical clotrimazole O: ITZ hepatotoxicity developed, stopped treatment; clinical signs recurred; treated with topical clotrimazole and oral enrofloxacin; clinically normal within 10 days.
8 yr, MN, DSH with sneezing, epistaxis ^{153a}	Unilateral nasal, sinonasal <i>Aspergillus</i> or <i>Penicillium</i> infection	I: None C: None for fungus	Multifocal inflammation with fungal hyphae	CT: left nasal cavity	T: 4 mos ITZ O: Resolved for 8 mos after therapy stopped
9 yr, MN, Persian with purulent nasal discharge, periocular swelling ^{153a}	Unilateral nasal mass and inflammation	I: AGID negative for <i>A. fumigatus</i> C: None	Chronic active inflammation with bone loss and hyphae	CT: fluid and mass unilateral in nasal passage, punctate bone lysis	T: 10 wks ITZ then fluconazole at relapse O: Resolved but then recurred 8 mos later
4 yr, MN, Himalayan with chronic purulent nasal discharge ^{153a}	Bilateral fungal rhinitis	I: None C: <i>A. niger</i>	Inflammation and disseminated fungal hyphae	CT: bilateral fluid and soft tissue accumulation, areas of bony lysis	T: 2 mos itraconazole, developed toxicity O: Recovered, one episode 9 mos later
8 yr, Sex not reported, sneezing and unilateral epistaxis ^{153a}		I: None C: None	Inflammation with fungal hyphae	CT: masses in both nasal cavities	T: ITZ just started O: No long-term follow-up available yet

MN, Male neutered; FS, female spayed; URI, upper respiratory infection; CT, computed tomography; AGID, agar gel immunodiffusion; IEP, serum immunoelectrophoresis; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; ITZ, itraconazole

Infectious Diseases of the Dog and Cat, 3rd Edition

Disseminated aspergillosis in people is usually secondary to immunodeficiency or immune suppression, although invasive *Aspergillus* has been described in immunocompetent individuals.⁶⁹ The most common underlying predisposing factors are leukemia, neutrophil or macrophage dysfunction, neutropenia, acquired immunodeficiencies, and prior chronic antibacterial therapy.¹ The protective immune response to *Aspergillus* has been well characterized in murine models of infection and includes a variety of innate mechanisms (e.g., expression of Toll-like receptor-2 by pulmonary dendritic cells) in addition to T-helper cell (Th)1-regulated adaptive immunity characterized by the production of cytokines such as interleukin (IL)-18, IL-12, tumor necrotizing factor (TNF)- α , and interferon- γ (IFN- γ). Individuals that have dominant Th2 immunity develop progressive disease, and glucocorticoid therapy is known to stimulate Th2-driven immune responses.^{7,22,82} In an experimental system, mice vaccinated with *Aspergillus* antigens developed a protective Th1 immune response; however, vaccination for aspergillosis is unlikely to have a role in a clinical setting.²¹ In experimental infections, a sonicate vaccine given before the administration of glucocorticoids protected mice against lethal pulmonary aspergillosis.⁶²

Predisposing factors for canine aspergillosis may include a combination of optimal climatic conditions, an access to particular strains of *Aspergillus*, and a subtle defect in mucosal immunity that may have a genetic basis.³³ German shepherd dogs are also susceptible to disseminated infection, with a range of other opportunistic fungi.¹⁵³ Glucocorticoids should never be administered to dogs with aspergillosis, and their inadvertent use has precipitated dissemination of the infection in some cases.

64.3.2 Clinical Findings

Disease involves multiple organ systems and develops over several months, but most dogs are terminally ill when first examined. The most consistent clinical features are vertebral pain progressing to paraparesis, paraplegia, or limb lameness with pronounced swelling and discharging sinus tracts. A sudden onset of paraplegia may result from rupture of an infected intervertebral disk or vertebral subluxation from instability.

Other nonspecific clinical signs include anorexia, weight loss, muscle wasting, pyrexia, weakness, lethargy, and vomiting. Occasionally, dogs have clinical evidence of CNS involvement, lymphadenomegaly with cutaneous edema, and pyometra. Uveitis or endophthalmitis may be clinically apparent some months before generalized illness develops and thus may be important in early diagnosis.

Although uncommon, aspergillosis can also infect body cavities, either from hematogenous spread, or from local extension from a penetrating wound or foreign body. Further systemic spread can occur from these sites. Pericarditis and associated effusion can result in signs of right-sided heart failure such as abdominal distention from a modified transudate.¹⁷ It can arise from rupture of a myocardial abscess, contiguous spread from the lung or hematogenous source. Intraabdominal infections can result from a perforating bowel or transabdominal catheter placement or penetrating wounds. Fever, GI signs, abdominal distention, and anorexia are the most common findings with abdominal infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

64.3.3 Diagnosis

64.3.3.1 Clinical Laboratory Findings

The most consistent hematologic abnormality is the presence of mature neutrophilia. Eosinophilia or monocytosis may be apparent. Biochemical analysis may reveal elevations in total protein concentration, serum urea, and serum alkaline phosphatase (ALP), ALT, and amylase activities. Radiography of affected long bones reveals areas of lysis and cortical destruction, with similar changes in sternebrae and vertebral bodies associated with diskospondylitis (Fig. 64-10, A and B). In the few cases with bronchopulmonary involvement, interstitial alveolar or consolidated alveolar patterns have been observed.²⁴

623

624

Fig 64-10 Canine disseminated aspergillosis. A, Radiograph of humeral lesion. Note extensive cortical destruction and new bone formation. B, Diskospondylitis in a dog with disseminated aspergillosis. (Courtesy Michael Day, University of Bristol, North Somerset, United Kingdom.)

64.3.3.2 Organism Identification

Methods to detect *Aspergillus* include cytology, culture, and histopathology. An effective and simple diagnostic test involves examination of an aseptically collected urine sample for the presence of hyphal elements (Fig. 64-11). Urinary tract *Aspergillus* infections are generally a consequence of hematogenous

Infectious Diseases of the Dog and Cat, 3rd Edition

spread and are usually observed in immunocompromised hosts. Fungal elements may also be observed on cytologic examination of blood, synovial fluid, lymph node, bone, or intervertebral disk material. Confirmation of fungal involvement by culture on Sabouraud's dextrose agar requires at least 5 to 7 days.

64.3.3.3 Antibody Testing

Because *Aspergillus* is ubiquitous, establishing a definitive diagnosis by measuring serum antibodies can be confusing if other results of diagnostic modalities are not considered during the evaluation. Several methodologies are available to measure *Aspergillus*-specific antibodies in serum. The AGID, CIE, ELISA, and fluorescent antibody (FA) test may provide rapid serologic confirmation, but not all dogs with disseminated infection have detectable *Aspergillus* antibodies. For example, kits using *A. fumigatus* as an antigen may not detect antibodies in dogs with disseminated infection caused by *A. terreus*.¹³⁶ Serologic responses can have positive results in animals that are exposed to the fungus but not persistently infected. Titers may be relatively lower in these animals.⁴⁵ For further information on laboratories and test kits for antibody assays, see [Appendices 5](#) and [6](#), respectively.

624

64.3.3.4 Antigen Detection

In people with invasive aspergillosis, efforts to detect *Aspergillus* antigens in body fluids have focused on detection of *Aspergillus* galactomannan (GM) or other carbohydrates in serum, cerebrospinal fluid (CSF), respiratory washings or urine by latex agglutination (Pastorex *Aspergillus* latex agglutination test; Sandofi Diagnostics Pasteur, Marnes-La-Coquette, France) or ELISA (Platelia™ *Aspergillus* EIA; Sandofi Diagnostics Pasteur, Marnes-La-Coquette, France and Bio-Rad Laboratories, Redmond, Wash.) or immunoblot methods.^{61a,120,147} This component of the polysaccharide cell wall of the organism is released in viable quantities in body fluids during fungal growth in tissues. False-negative results in serum correspond to low test sensitivity, whereas false-positive results in urine correspond to reaction to other fungi and organisms causing urinary tract infections.^{68,140,155} In people, ELISA tests are more sensitive and reproducible than are latex methods. Furthermore, the presence of serum *Aspergillus* antibody may interfere with the ELISA test.⁵⁸ Rising GM levels have been associated with treatment failures in patients with invasive aspergillosis.⁹ Application of tests for GM for the diagnosis of canine aspergillosis has been limited.⁴⁵ Detection of GM levels was inconsistent in dogs with disseminated disease.

64.3.3.5 Genetic Detection

The application of polymerase chain reaction (PCR) to diagnosis is now becoming more widespread in human medicine, and it has been applied to samples of whole blood, serum, urine, CSF, and bronchoalveolar lavage fluid. A range of target genes are used, including those within the 18S, 5.8S and 28S rDNA gene complex that are relatively conserved among fungal species, mitochondrial genes, and the variable sequences of the intervening internal transcribed spacer regions.^{64,107} In one case of canine disseminated aspergillosis, the identity of the organism was confirmed by partial sequencing of 18S rDNA.¹¹¹ In people, positive PCR results were comparable to those of serum GM levels.¹¹ Quantitative (real-time) PCR has been used to monitor infectious load in human patients with invasive aspergillosis, and the increased sensitivity of this assay permits an earlier diagnosis (by days to weeks) compared with serologic methods.^{67,159} PCR results may be positive in patients that are culture negative,¹⁰⁸ and PCR-positive people with invasive aspergillosis become PCR negative after successful treatment.⁸⁰ Additional studies will be needed to determine if PCR is a sensitive and reproducible predictor of disseminated illness.

64.3.4 Pathologic Findings

Gross changes include focal osteomyelitis and multiple, pale granulomas in kidneys and spleen that may also be seen in lymph nodes, myocardium, pancreas, and liver. Occasionally, pulmonary congestion or GI mucosal reddening or erosions may be found. Microscopic granulomas may be associated with areas of slow vascular flow in liver, lungs, eyes, and pancreas and occasionally in prostate, thyroid, uterine submucosa, and brain. Infarcted areas secondary to thrombi containing fungal elements have been found in spleen, kidneys (Fig. 64-12), and liver. Lesions are granulomatous and contain varying numbers of septate, branching hyphae that may have characteristic lateral branching aleuriospores (Fig. 64-13, A). Intralesional hyphae are best visualized by periodic acid-Schiff or Gomori's methenamine silver stain, and they have been identified by immunostaining with specific antisera (see Fig. 64-13, B).^{15,106} The cellular infiltrates may be predominantly neutrophilic or may also include macrophages, giant cells, lymphocytes, and plasma cells.^{34,106}

Infectious Diseases of the Dog and Cat, 3rd Edition

64.3.5 Therapy and Prognosis

Severely ill dogs have poor prognoses. Treatments, including supportive therapy of fluids and antibiotics, together with thiabendazole or KTZ with and without concurrent 5-fluorocytosine, have been unsuccessful. Hamycin, an experimental polyene related to AMB, showed partial effectiveness in treating one dog.⁷⁰ Only two systemic antifungals have shown evidence of efficacy to date: AMB and ITZ (Table 64-3). The potential fungicidal and immunomodulatory effects of AMB are counterbalanced by its nephrotoxicity, which limits its use in patients with renal dysfunction. This problem has been addressed by the use of novel delivery systems that enhance uptake of the drug by reticuloendothelial cells at sites of inflammation and reduce accumulation in the kidneys. These formulations are AMB-lipid complex (Abelcet, Liposome Co., Princeton, N.J.), AMB-colloidal dispersion (Amphocil/Amphotec, Sequus Pharmaceuticals, Menlo Park, Calif.), and liposome-encapsulated AMB (AmBisome, Fujisawa Healthcare, Deerfield, Ill. and Nexstar, San Dimas, Calif.).⁴¹ AMB-lipid complex has been used to treat disseminated aspergillosis in people^{22a} and has been evaluated in companion animals, but use is limited by expense. An alternative intravenous lipid formulation has proven efficacious in the treatment of canine leishmaniasis but has not been evaluated for aspergillosis.⁷⁶ New lipid delivery systems are currently under development, for example, cochleate lipid cylinders that are a lipid bilayer sheet rolled into a spiral without internal aqueous space.¹⁵¹

Fig 64-12 Canine disseminated aspergillosis. Sagittal section of kidney with fungal mass in renal pelvis and scattered fungal granulomata (*A. terreus*). (Courtesy Michael Day, University of Bristol, North Somerset, United Kingdom.)

Infectious Diseases of the Dog and Cat, 3rd Edition

The induction of long-term clinical remission has been achieved in four dogs with oral ITZ (5 to 10 mg/kg daily for up to 1095 days).^{72, 153} In one dog, the infection was eliminated; others had resolution of clinical illness but eventually died from disseminated aspergillosis after therapy was discontinued. One dog was euthanized while improving clinically during treatment because of radiographic evidence of additional spondylitic lesions. The surviving dog was not a German shepherd. In people with disseminated aspergillosis, ITZ is also a useful drug in treatment, but similar failures or relapses are common in the most immunocompromised patients.³⁹

Because azole-resistant strains of *Aspergillus* and other fungi are now recognized, a new generation of triazole drugs has now been developed for human medicine. Voriconazole, posaconazole, and ravuconazole all have

625

626

activity against *Aspergillus* spp.¹⁵⁰ These agents have not yet been tested in companion animal patients. Terbinafine, an allylamine drug that inhibits fungal sterol synthesis, has been used to treat resistant disseminated aspergillosis in people, alone and in combination with other antifungal drugs. Use of this drug in treating fungal infections in dogs and cats has been empirical and requires further studies on efficacy. A new class of antifungal drug, the β -glucan synthase inhibitors (e.g., caspofungin), acts by blocking synthesis of 1,3- β -D-glucan, a component of fungal cell walls that is not found in mammalian cells. Caspofungin is efficacious in invasive aspergillosis of people but has not been evaluated in veterinary species.⁷¹ Combination therapy that uses AMB with azoles, flucytosine, or rifampin has been beneficial in in vitro and in some animal experiments, but further use in invasive disease of people is needed to confirm efficacy. Caspofungin has been used in combination with ITZ in effectively treating invasive aspergillosis in people.¹¹⁴ See [Chapter 57](#) and the Drug Formulary, [Appendix 8](#), for more information on these drugs.

Fig 64-13 Canine disseminated aspergillosis. A, Fungal granuloma in pancreas (H and E stain, $\times 140$). B, Fungal hyphae within a granuloma marked with antiserum to *A. terreus* (Fluorescent antibody, $\times 320$). (Courtesy Michael Day, University of Bristol, North Somerset, United Kingdom.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 64-3 Therapy for Disseminated Aspergillosis

DRUG ^a	SPECIES	DOSE ^b (mg/kg)	ROUTE	INTERVAL (HOURS)	DURATION
Amphotericin B (deoxycholate)	D	0.25	IV	48	^c
Itraconazole	D	2.5–5.0	PO	12	prn ^d
	C	10	PO	24	prn ^d
Amphotericin B lipid complex	D	2–3	IV	3 days per wk	^e
	C	1	IV	3 days per wk	^f
Terbinafine	D	5	PO	12	prn ^g

D, Dog; B, dog and cat; C, cat; IV, intravenous; PO, by mouth; prn, as needed.

a For additional information, see Drug Formulary, [Appendix 8](#).

b Dose per administration at specified interval.

c Until a cumulative dose of 4 to 8 mg/kg is reached for cats and 8 to 12 mg/kg for dogs.

d Therapy to control infection may require months to years, although clinical remissions may be achieved; the infection may reactivate in a variable time period after discontinuing treatment.

e For a total of 9 to 12 treatments until a cumulative dose of 24 to 27 mg/kg is reached.

f For a total of 12 treatments until a cumulative dose of 12 mg/kg is reached.

g Extrapolated human dose. Tablets may have to be reformulated to achieve this dose level. No dog studies on pharmacokinetics or studies of efficacy with aspergillosis have been conducted.

Immunomodulatory therapy (e.g., recombinant cytokine therapy) is sometimes used as an adjunct treatment in human invasive mycotic disease, and although such agents are available for use in the dog (e.g., recombinant granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) they have not been applied to cases of canine disseminated aspergillosis.^{18,43}

64.4 FELINE DISSEMINATED ASPERGILLOSIS

Michael J. Day

Feline aspergillosis largely occurs in cats up to 2 years of age, although, in one study, the majority of affected cats were middle aged to older. No clear breed predispositions have been discovered. Unlike dogs with aspergillosis, most affected cats have concurrent immunosuppressive diseases, such as panleukopenia, feline infectious peritonitis, FeLV infection, or multiple diseases, or they have had dystocia or have been receiving glucocorticoid or antibiotic therapy.⁹⁸ Aspergillosis has not been reported in cats with feline immunodeficiency virus (FIV) infection, although such cats may have other opportunistic mycoses.¹⁶ Cats infected with FeLV or FIV had a greater diversity of fungal genera cultured from their skin or mucous membranes compared with noninfected control cats. Clinical signs are referable to GI or pulmonary involvement, with nonspecific findings similar to those in dogs. Hematologic findings are variable and may reflect other underlying diseases. Feline aspergillosis is so uncommon that treatment options have not been extensively reviewed. Rare cases of localized *Aspergillus* infection have recovered following complete surgical débridement of affected tissue.

Diagnosis is often made at necropsy, and findings may include pulmonary granulomata, GI ulcers, or pseudomembranes and involvement of urinary system or CNS. The lesions are characterized by hemorrhage and

626

627

Infectious Diseases of the Dog and Cat, 3rd Edition

necrosis, with variable numbers of inflammatory cells and fungal hyphae that may invade blood vessels, leading to thrombosis.

65 CHAPTER 65 Candidiasis and Rhodotorulosis

Craig E. Greene

Francis W. Chandler

65.1 CANDIDIASIS

65.1.1 Etiology

Members of the genus *Candida* are dimorphic fungi in the family Cryptococcaceae. In the yeast phase, *Candida* species normally inhabit the alimentary, upper respiratory, and genital mucosae of mammals. A sexual stage has not been identified, and the small (2- to 6- μ m), thin-walled, ovoid, yeastlike cells (blastoconidia) reproduce by budding. Not all *Candida* species are adapted to colonize normal mucosae. *Candida* species, especially *Candida albicans* and *Candida parapsilosis*, have been the most commonly cultured fungi from the ears, nose, oral cavity, and anus of clinically healthy dogs. In contrast, in cats with or without retrovirus infections, *Candida* species were less commonly isolated from the oropharyngeal mucosa (5.9%) or haircoat (9.4%) than other fungi.³⁹ Occasionally, *Candida tropicalis*, *Candida pseudotropicalis*, *Candida guilliermondii*, and *Candida krusei* have been found on human and animal body surfaces. These four species require an immunocompromised host to effectively colonize the mucosae and produce disease. In one study of *Candida* urinary infections, *C. albicans* was the most common isolate from dogs and cats, whereas *Candida rugosa* and *C. krusei* were only isolated from dogs, and *Candida* (previously *Torulopsis*) *glabrata* and *C. parapsilosis* were only isolated from cats.³⁵ *Candida* species become more prevalent in environments where people or animals live. Only rarely are *Candida* species isolated from soil or as laboratory contaminants.

C. glabrata is part of the normal microbial flora of the skin and mucosal surfaces of people and animals and is an environmental saprophyte. It is considered to be a nonpathogenic inhabitant of mucosal surfaces, but in immunosuppressed animals, clinical illness can occur. *C. glabrata* is different from other *Candida* species because of its nondimorphic blastoconidial morphology and haploid genome.

65.1.2 Epidemiology

Candida species, first acquired by neonates as they pass through the birth canal, colonize the oral, gastrointestinal (GI), upper respiratory, and genital mucosae for the life of the animals, but their presence normally evokes no reaction. The intact skin is an abnormal site for *C. albicans* except at mucocutaneous junctions of body orifices. Opportunistic infections may result if the skin becomes chronically traumatized or moistened. Under certain circumstances, *Candida* species also can invade deeper host tissues and proliferate as blastoconidia, pseudohyphae, and branched, septate hyphae. In other instances, they may disseminate via the blood stream to many tissues.

C. glabrata has been implicated more frequently as the cause of nosocomial infections in immunocompromised and neutropenic human patients.⁴³ As with other *Candida* species, it can be cultured from surfaces in the hospital environment. Hospitalized human or animal patients may become colonized with *Candida* organisms during their hospital stay from contact with contaminated surfaces or during medical diagnostic or therapeutic procedures. Urinary tract infections (UTIs) have been observed in immunocompromised dogs and cats. The yeast gains access to the genitourinary tract from local contamination and ascending infection or from embolic

Infectious Diseases of the Dog and Cat, 3rd Edition

spread to the kidneys in disseminated infection. Disseminated infections are not as common but are associated with similar immunosuppressive conditions. Immunosuppression or chronic antibacterial therapy contributes to colonization and subsequent overgrowth of the fungus.

628

65.1.3 Pathogenesis

Pathogenic factors of *Candida* species are important in determining their relative virulence in the host. *C. albicans* can colonize and invade stratified squamous epithelia with varying degrees of keratinization and columnar epithelia in the intestines. *C. albicans* is also the most polymorphic species of the genus; whereas yeast cells can colonize epithelia, hyphae are thought of as the more invasive forms and are found with deeper tissue invasion. Hyphae of this organism consistently adhere more readily than yeast cells to host epithelial tissues. When cells of *C. albicans* enter the blood stream, they become rapidly coated with host platelets as a result of fibrinogen-binding ligand. This coating likely reduces the immune-visibility of the fungus to the host, thereby allowing dissemination.

Local proliferation of *Candida* species in wounds or on mucosal surfaces is the first step in the spread of infection. Overgrowth of *Candida* is probably inhibited under most circumstances by various factors, including intestinal, genital, and cutaneous microflora. Factors that upset the balance of normal endogenous microflora, such as prolonged broad-spectrum antibiotic therapy, may allow *Candida* organisms to proliferate, especially in the external auditory meatus, oropharynx, and GI tract.^{26,41} Similarly, disruption of cutaneous or mucosal barriers by burns, surgery, cytotoxic agents, trauma, or indwelling vascular or urinary catheters provides a pathway for *Candida* organisms to enter the body from the body surfaces or the environment. Intestinal candidiasis may be a sequela to parvoviral infections^{31,38} or alterations in microflora caused by antibacterial chemotherapy.⁴⁴ Dogs and cats may be more likely to contract urinary tract candidiasis from (1) increased intestinal colonization, such as after antimicrobial use or viral enteritis; (2) decreased cellular immunity from glucocorticoids or cytotoxic agents, irradiation, or granulocytopenia; or (3) alterations in the urinary environment, such as those caused by glucosuria, an altered pH, dilute urine, a bacterial infection, urolithiasis, neoplasia, urethrostomy, cystostomy, indwelling catheters, or urinary stasis.^{17,35}

Bull terriers with lethal acrodermatitis are known to have impaired T-cell function and have been shown to harbor higher numbers of *Malassezia* and *Candida* organisms on their skin, especially at lesion sites.²⁵ *C. albicans* was frequently isolated from lesional skin and haircoat, mucous membranes, nails, and foot pads from affected dogs but not from control healthy dogs or those with atopic dermatitis. Fungal hyphae or pseudohyphae were demonstrated in lesions of hyperkeratosis of the foot pads and nail dystrophy.

Cell-mediated immunity (CMI) and circulating neutrophils appear to be major defenses against disseminated candidiasis. Multinucleated giant cells containing fungal organisms can be observed within lymph nodes and lymphatic vessels draining the mucosal lesions and may provide a mechanism for dissemination. Once in the body, CMI appears to be an important determinant of additional spread of infection. Evidence also shows that mannan, a *Candida* cell wall glycoprotein, has immunosuppressive properties that facilitate persistent intracellular infection. As with surface infections, prolonged immunosuppression, cytotoxic chemotherapy causing persistent neutropenia, diabetes mellitus, long-term glucocorticoid therapy, and prolonged antibiotic therapy have resulted in an increased incidence of disseminated candidiasis in people. Candidiasis has developed in dogs with experimentally induced and spontaneous neutropenia.² Similar predispositions have not been substantiated for the occurrence of disseminated candidiasis in cats. However, a cat with disseminated infection had concurrent toxoplasmosis, diabetes mellitus, and suspected hyperadrenocorticism.^{12,42}

Infectious Diseases of the Dog and Cat, 3rd Edition

In disseminated candidiasis, the microcirculation in tissues, such as lungs, skin, kidneys, liver, brain, myocardium, eyes, intervertebral discs, and skeletal muscle, filters and clears the blood of yeasts. This activity results in embolic colonization and microabscess formation at these sites.

65.1.4 Clinical Findings

Localized candidiasis is found in chronically immunosuppressed dogs and cats and in those with nonhealing ulcers of the oral, upper respiratory, GI, or genitourinary mucosae. Clinical signs reflect the anatomic location and extent of the mucosal damage (Table 65-1). Lesions are characterized by nonhealing ulcers covered by whitish-gray plaques with hyperemic margins. A white vaginal or preputial discharge may be seen in candidiasis of the genital mucosa. Dysuria and hematuria are features of *Candida* urocystitis (Fig. 65-1).¹¹ Some urinary infections are subclinical. Chronic lesions of the skin or nail beds may appear as nonhealing, erythematous, moist, greasy exudations, and crusting (Fig. 65-2).²⁹ Pruritus varies. Crusts may be superficial and may be peeled off to reveal eroded skin. Superficial ocular infections appear as conjunctival congestion and corneal ulceration.¹² Chronic otitis externa characterized by erythema, exudation, and pruritus, may be apparent.^{26,32}

Disseminated candidiasis has been recognized in dogs and cats. Although clinical signs frequently reflect involvement of particular organ systems, lesions in dogs and cats with multisystemic infections are often widespread.¹⁷ Fever and the sudden appearance of multiple raised erythematous to hemorrhagic skin lesions have been described in canine systemic candidiasis. The lesions begin as small wheals or macules that eventually ulcerate (Fig. 65-3). Pain and reluctance to move are common manifestations of myositis. Dogs with systemic candidiasis also have peripheral lymphadenomegaly and fistulous drainage resulting from underlying osteomyelitis. Cats with systemic infections have developed uveitis, chorioretinitis, neurologic deficits, and pleural effusions.¹² Enophthalmitis has also been observed in a dog,²² and intraocular infections are considered sequelae to disseminated infections.

65.1.5 Diagnosis

Hematologic findings usually are normal in localized infections; however, leukopenia and thrombocytopenia may be associated with disseminated disease. Muscle and liver enzyme concentrations may be increased, depending on the tissues affected. Cytologic examination of impression smears, aspirates of the lesions, or urine sediment, may reveal the yeast cells (see Fig. 65-1).

Isolation methods, which first involve lysis centrifugation, release fungi from leukocytes, increasing the ability to grow *Candida* species and decreasing the time between inoculation and growth of the organism. *Candida* species grow well on blood agar, therefore they are often isolated from specimens submitted for bacterial culture. *Candida* grow rapidly at room temperature or 37° C (98.6° F), producing smooth or wrinkled, creamy white, yeast colonies. Colonies are composed of spherical to oval yeast cells that are 5 to 7 µm in diameter (Fig. 65-4), pseudohyphae, and septate hyphae that are 3 to 5 µm wide. Pseudohyphae are composed of elongated yeast cells that remain attached end to end in chains. They can be distinguished from true hyphae by their prominent constrictions at points of attachment between adjacent cells. Septate hyphae are tubular with parallel contours. The thick-walled chlamydoconidia, 8 to 12 µm in diameter, are spherical. *C. albicans* is also identified by a positive germ tube test (see Fig. 56-17 and associated text) and patterns of carbohydrate metabolism.

Infectious Diseases of the Dog and Cat, 3rd Edition

Antemortem blood samples for culture are best obtained from peripheral arteries, because most of the organisms, effectively filtered out by tissues, never reach the systemic venous circulation. Because consistent renal embolization occurs with disseminated infection, *Candida* species are more easily isolated from urine than from the blood. Candiduria in patients without lower urinary tract signs or indwelling urinary catheters usually reflects hematogenous spread to the kidneys. Recovery of *Candida* species from a normally sterile fluid such as cerebrospinal fluid or joint fluid is indicative of invasive candidiasis. Organisms may sometimes be cultured from many tissues at surgery or necropsy, but such results should be interpreted cautiously. Culture of *Candida* species from cutaneous or mucosal surfaces or exudates alone should not be considered an absolute indicator of infection. Histologic confirmation of invasion and host reaction are essential. Cutaneous or mucosal biopsy specimens should be submitted for histologic and cultural examinations simultaneously. Biopsies of liver, spleen, lung, and kidney may be needed to document hematogenous spread. A definitive histologic diagnosis can sometimes be made in the presence of negative culture results.

Fig 65-4 Culture of *Candida* species from urinary infection showing variable-size budding yeasts (Lactol Phenol Cotton Blue stain, $\times 100$). (Courtesy University of Georgia, Athens, Ga.)

Numerous nonculture methods have been developed for the diagnosis of disseminated candidiasis in serum, whole blood, or urine specimens.³⁶ D-arabinitol, a low molecular weight metabolite, is occasionally increased in serum of humans with disseminated candidiasis. Artifactual increases of D-arabinitol that develop during renal failure are identified by comparing its concentration with that of serum creatinine.

As a more rapid alternative to culture methods, the polymerase chain reaction (PCR) has been used to detect *Candida* species in blood and urine.^{28,28a} PCR of urine from dogs allowed for direct detection of *Candida* within 2 days.²⁰ Numerous tests also have been developed on an experimental basis to detect soluble antigens of *Candida* species such as mannan in blood and urine using the enzyme-linked immunosorbent assay (ELISA) and latex agglutination (LA) immunoassay.¹⁶ Two LA tests are commercially available for clinical detection of

Candida antigens in body fluids: Pastorex *Candida* (Sanofi Diagnostics Pasteur, Marres-la Coquette, France) and Cand-Tec (Ramco Laboratories, Inc., Houston, Tex.).

65.1.6 Pathologic Findings

Animals that die of disseminated candidiasis have gross lesions consisting of multiple white foci in the heart, liver, spleen, lymph nodes, central nervous system, kidneys, or other organs. Microscopic evaluation reveals multifocal abscesses or areas of necrosis that contain abundant blastoconidia (budding, yeastlike cells), pseudohyphae, and true hyphae surrounded by mixed inflammatory cells (Fig. 65-5). Infiltrates are usually minimal in profoundly immunosuppressed or leukopenic animals. Occasionally, hyphal angioinvasion or occlusion of small and medium-size arteries by systemic candidal emboli results in nodular, hemorrhagic infarcts.

Caution must be exercised in diagnosing localized, superficial candidal infections on the basis of cytologic or histologic study of mucocutaneous lesions unless invasive hyphal elements and numerous inflammatory cells are present (Fig. 65-6). The different *Candida* species are morphologically and tinctorially indistinguishable in clinical specimens. Culture is needed for definitive species identification. Test kits are available to confirm genus identity in clinical or culture specimens (see Appendix 6).

In smears and sections of infected tissue, *C. glabrata* closely resembles *Histoplasma capsulatum*, but they do have some distinguishing characteristics. In tissues stained with hematoxylin-eosin (H and E) stain, *C. glabrata* does not show the pseudocapsule, or “halo,” effect shown by *H. capsulatum*. With Gomori's methenamine silver (GMS) stain, *C. glabrata* are larger, bud more frequently, are more often extracellular, and are not in clusters. Unlike other *Candida* species, *C. glabrata* reproduces only by budding and is always a yeast form in tissue or culture.

Infectious Diseases of the Dog and Cat, 3rd Edition

65.1.7 Therapy

Treatment of superficial candidiasis involves drying of nonmucosal lesions. Antifungal susceptibility testing is unreliable. Skin lesions can be treated by systemic azoles and shampoos containing chlorhexidine, azoles, and selenium sulfide. Topical therapy may need to continue for up to 8 weeks.

Mucosal lesions can be treated with topical nystatin, gentian violet (1:10,000), or topical amphotericin B (AMB) lotions (Table 65-2). However, treatment of mucocutaneous candidiasis is generally dominated by the azole antifungal drugs, and they can be used topically or systemically. Intravesicular administration of clotrimazole was used to treat a *Candida* UTI in a cat.⁴² Lufenuron also has been used to treat cutaneous infections.⁴ In a diabetic hypothyroid dog with a UTI caused by systemic drug-resistant *C. albicans*, local intravesicular infusion of clotrimazole was successfully used.¹⁰ Previous treatment with fluconazole (FCZ), terbinafine, and flucytosine (FCY) was unsuccessful. AMB, which is usually effective against *C. albicans*,³⁷ was contraindicated in this dog. Similarly, intravesicular administration of clotrimazole was successful in controlling UTI in a cat with diabetes mellitus and iatrogenic hyperadrenocorticism and *C. glabrata* infection.⁴² Unfortunately, with intravesicular infusions, infection above the bladder cannot be controlled unless systemic therapy is used. Systemic antifungal therapy is generally reserved for renal parenchymal disease and is not often effective against lower urinary tract fungal infections because of the low concentrations of polyene and azole drugs in the urine. Use of FCY may be beneficial in these cases because it reaches a high concentration in the urine. Voriconazole (VCZ), a newer antifungal in this class, is equally as effective against *Candida* but is not widely available (see Drug Formulary, Appendix 8). Clotrimazole infusions may be effective in treating *Candida* lower UTIs; however, if the infection is deeper in the kidney than the renal pelvis or within the wall of the bladder or ureters, infection may not be effectively controlled without simultaneous topical infusion along with systemic antifungal administration. Urinary acidifiers such as methenamine derivatives may be helpful because they produce a low pH that inhibits fungal growth. For additional information on the bladder infusion method, see Table 65-3 and clotrimazole in Drug Formulary, Appendix 8.

Table 65-2 Recommended Drugs for Topical Treatment of Dermal Candidiasis and Trichosporonosis

DRUG GENERIC (BRAND)	FORMULATION	INTERVAL (HOURS)	DURATION (WEEKS)
Nystatin (Nilstat)	100,000 U/g	8–12	1–2
Miconazole (Conofite)	2%	12–24	2–4
Clotrimazole (Lotrimin) ^a	1%	6–8	1
Amphotericin B (Fungizone)	3%	6–8	1

a For intravesicular infusion in the treatment of cystitis, see text and Drug Formulary, [Appendix 8](#).

Treatment of lower UTIs caused by *C. glabrata* would involve local infusion of antifungal solutions, although systemic antifungal therapy, as outlined for candidiasis, would be more convenient and appropriate should disseminated infections be diagnosed. Unfortunately, *C. glabrata* is innately resistant to azole antimycotic agents. AMB or FCY must be used at higher levels.^{9,37} FCY should only be used in combination with another antifungal cell-wall active drug such as AMB. Lipid formulations of AMB might be considered; however, the urinary excretion of these drugs is lower than with unmodified AMB. Higher levels of FCZ would be needed for treating UTIs caused by *C. glabrata* than by the other *Candida* species ([Table 65-4](#)).

Systemic candidiasis is the most refractory form of infection. Animals with systemic candidiasis should always be evaluated for uveitis or chorioretinitis, because intraocular localization is difficult to resolve. Systemic candidiasis can be treated with intravenous (IV) AMB, but the drug's nephrotoxicity in otherwise compromised hosts can be fatal. Lipid formulations of AMB are relatively effective and recommended for conditions in people for whom expense is less of a concern. Ketoconazole (KTZ) and other related benzimidazoles are currently the drugs of choice for treating infected dogs (see [Table 65-4](#)). Supplemental oral administration of vitamin A might be recommended in any form of candidiasis because it has been shown to increase resistance to infection by *Candida* species.

Caspofungin, the first echinocandin antifungal agent, has activity against *Candida* and *Aspergillus* species. It is only available as a parenteral preparation, and dosages for dogs and cats are not available. VCZ, the previously mentioned newer azole, is effective against FCZ-resistant strains of *Candida*.³³

65.2 RHODOTORULOSIS

Yeasts of the genus *Rhodotorula* are saprophytes, found in domestic environments on shower curtains, in bathtub grout, and as commensals of moist skin. They can be isolated as environmental or dermal contaminants and are rarely isolated from clinical specimens of the urinary tract or surgical wounds. Granulomatous epididymitis was associated with this infection in a dog,¹⁹ and disseminated infections have developed in immunocompromised people.¹

This yeast may gain access to the genitourinary tract through local contamination. The yeast has caused septicemia and meningitis in people on long-term IV therapy. Contamination of IV catheter sites is the presumed route of these infections.²³ As with candidiasis, immunocompromised states are associated with disseminated infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 65-3 Protocol for Infusing Urinary Bladder of Dogs and Cats with Clotrimazole^a

1. Put animal under general anesthesia and in dorsal recumbency.
2. Cleanse genitalia with physiologic saline.
3. Insert balloon-tipped (Foley) catheter, where possible, and inflate cuff.
4. Attach three-way stopcock and remove urine from the bladder through this port.
5. Attach syringe containing 1% clotrimazole.^b
6. Infuse 5 to 10 ml/kg while palpating bladder to avoid overdistention.
7. Keep solution inside urinary system for 15 to 25 minutes.
8. Rotate animal for several minutes on each side to ensure contact with all urinary bladder surfaces.
9. Recover animal from anesthesia.
10. Keep catheter in place until animal voids spontaneously.
11. Deflate cuff and remove catheter at the appropriate time.
12. Provide at least three to four treatments, 1 week apart.
13. Check urinalysis each week and monthly thereafter to ensure yeasts are not found in sediment. Repeat clotrimazole-infusion if infection is still present.
14. Repeat fungal culture after third treatment.
15. Repeat fungal culture 1 to 2 months after last treatment.
16. Recommend at least one treatment after yeasts are no longer visible.
17. Recommend concurrent fluconazole therapy because infection may ascend to the kidneys.

a Modified from Pressler BM, Vaden SL, Lane IF, et al. 2003. *Candida* spp. urinary tract infections in 13 dogs and seven cats: predisposing factors, treatment, and outcome. *J Am Anim Hosp Assoc* 39:263–270.

b Commercially available solution with polyethylene glycol 400.

Rhodotorula species can be isolated on routine mycologic media at room temperature after 3 to 4 days incubation. Colonies are smooth, are salmon pink, and contain 10 µm-diameter encapsulated yeasts. Biochemical characteristics have been described.¹⁹

D, Dog; C, cat; B, both; H, human; PO, by mouth; IV, intravenous.

- a For additional information on these drugs, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c May have to extend therapy based on response.
- d Higher dosage within given range may be needed for systemic and urinary *C. glabrata* infections; however, increased risk of toxicity is more likely. Monitor animals by noting decreased appetite and increased serum ALT activity.
- e For additional information on amphotericin B dosing regimens, see Drug Formulary, [Appendix 8](#).
- f Always use in combination with a cell-wall-acting drug such as amphotericin B or an azole.
- g Dose per kilogram varies inversely with body weight (see Drug Formulary, [Appendix 8](#), for complete breakdown by weight).

In a dog with granulomatous epididymitis, severe swelling of the scrotum was observed.¹⁹ Treatment with antibiotics was ineffective, and the scrotum became firm. The testes and epididymides were surgically removed. The epididymides were swollen and when sectioned, were found to contain fibrous connective tissue, multifocal hemorrhages, and abscesses. On histopathologic examination, marked infiltration of neutrophils and macrophages with fibrosis was found in the dilated and partially ruptured ductus deferens. In surrounding stroma, focal collections of macrophages contained eosinophilic, spherical, 5- to 8- μ m diameter, yeastlike structures. The intracellular yeasts stained positive by periodic acid–Schiff and GMS procedures. Removal of the affected testes and epididymides was curative. In disseminated infections, systemic antifungal therapy, as for candidiasis, is indicated.

66 CHAPTER 66 Trichosporonosis

Craig E. Greene

Francis W. Chandler

66.1 ETIOLOGY

Trichosporon spp., yeastlike fungi that exist in nature as soil saprophytes, are members of the family Cryptococcaceae. In culture, they form hyaline yeastlike cells, mycelia, and characteristic arthroconidia. *Trichosporon* spp. are not considered to be primary pathogens because they are distributed in the environment worldwide and form a minor component of normal cutaneous and mucosal flora of people and animals. They cause superficial, cutaneous, and deep-seated mucosa-associated infections in immunocompetent hosts and disseminated, life-threatening infections in immunocompromised or postoperative patients.

The causative agent of disease was previously classified as *T. cutaneum*; however, taxonomic genomic analysis has indicated that six species (*T. asahii*, *T. asteroides*, *T. cutaneum*, *T. inkin*, *T. mucoides*, and *T. ovoides*) are important for human infections. The genus is also classified serologically into four types (I: *T. cutaneum*, *T. mucoides*; II: *T. asahii*, *T. asteroides*, *T. ovoides*; III: *T. brassicae*, *T. domesticum*; and also in I-III, *T. dulcitum* and *T. gracile*).

T. beigelii (= *T. cutaneum*), a transient skin commensal, is recognized as the agent of white piedra, a nodular mycosis of hair shafts affecting people, monkeys, and horses in temperate to tropical climates. A synergistic coryneform bacterial infection is often present in this condition, suggesting a pathogenic co-infection.³⁷ *T. beigelii*, along with *T. asahii* and *T. mucoides*, have been linked to the syndrome of human summer-type hypersensitivity pneumonitis in Japan^{22,25} and catheter-associated infections. *T. beigelii* has been found in the urine of human patients with indwelling urinary catheters and may be an opportunist in causing urinary tract infections (UTIs).¹⁶ *T. mucoides* was incriminated as a cause of nosocomial infection in children associated with a faulty bronchoscope.²⁸ *T. beigelii* was associated with outbreaks of mastitis in dairy herds.⁷ *T. capitatum* (= *Blastoschizomyces capitatus*, *Geotrichum capitatum*) has been incriminated as causing abortion in a cow and horse. Both *T. beigelii* and *T. capitatum* have caused systemic infections in people, especially in patients being treated for hematologic malignancies, in those with hereditary phagocyte deficiencies, and in recipients of renal and bone marrow transplants. *T. pullulans* and *T. beigelii* have caused infections in three cats. Biochemical and genetic studies indicate that cutaneous, mucosal, and environmental isolates differ from those that cause disseminated illness.^{14,17,29}

66.2 PATHOGENESIS

Most cases of trichosporonosis in people have been disseminated and fatal, and they have occurred in patients with severe immunosuppression who were also neutropenic. Many patients had received multiple or broad-spectrum antibiotics for documented or presumed bacterial infections, whereas others had neoplastic diseases or organ transplants. Presumably, the fungus invades mucosal surfaces of the respiratory, gastrointestinal, or urogenital tracts of immunosuppressed hosts, with subsequent dissemination. A few cases of valvular endocarditis caused by *Trichosporon* spp. have been reported.^{1,13} Phenotypic switching, a process by which pathogenic species of these

Infectious Diseases of the Dog and Cat, 3rd Edition

yeasts vary their surface characteristics and enzyme production, may be a way they avoid host defense mechanisms.¹¹

Feline infections have been characterized by mixed suppurative and granulomatous inflammation of the mucosal and submucosal or subcutaneous tissues. Evidence for immunosuppression has not been apparent in all affected cats, but one had multicentric lymphosarcoma.

66.3 CLINICAL FINDINGS

One cat was reported to have a fever, an inspiratory stertor, and a protruding unilateral nasal mass (Fig. 66-1) similar to that caused by *Cryptococcus neoformans*.¹⁰ Later spread to regional lymph nodes and pulmonary tissues was suspected. Another cat had a chronic ulcerative subcutaneous lesion at the site of a bite wound.⁴ A third cat suffered from chronic hematuria and dysuria as a result of chronic cystitis complicated by the yeast infection.⁴ Another cat in which *T. domesticum* was isolated also had persistent lower urinary tract signs of hematuria and dysuria.²⁷ In people, clinical findings are usually those of fungal sepsis, with fever that is unresponsive to antibiotic therapy. Cutaneous lesions, chorioretinitis, and signs referable to renal glomerular and pulmonary vascular localization are most frequent.

66.4 DIAGNOSIS

Mere culture of *Trichosporon* spp. from cutaneous or mucosal surfaces can be misleading because the organism is a normal constituent of the endogenous microflora in these areas. Biopsy with histopathologic confirmation of host reaction and invasion of the deeper tissues by characteristic fungal elements is more specific for documentation of pathogenicity. In the animals with UTIs, yeasts may be observed microscopically in the urine sediment.

Trichosporon spp. can be grown on Sabouraud's or Mycosel agar (Becton Dickinson Microbiology Systems, Cockeysville, Md.) at 25° C, and after several days, spreading cream-colored yeastlike colonies are formed. Wet-mount lactophenol blue-stained preparations show hyaline, septate hyphae, arthroconidia (10.4 × 2.5 µm), and pleomorphic blastoconidia (2.5 to 8.0 µm in diameter). The characteristic arthroconidia are produced by segmentation and fragmentation of hyphae. Unlike those of *C. neoformans*, blastoconidia of the *Trichosporon* spp. do not show a capsule when stained with mucin stains or India ink. The species are distinguished from each other by differences in various carbon and nitrogen sources for growth.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 66-1 Mass (arrow) protruding from the nostril of the cat with nasal trichosporonosis. (Courtesy University of Georgia, Athens, Ga.)

T. beigelii produces a heat-stable, cell-wall antigen that is similar to the capsular polysaccharide of *C. neoformans*. The latex agglutination test, used to detect cryptococcal capsular polysaccharide antigen (see [Chapter 61](#)), has been used to diagnose disseminated *T. beigelii* infection in people and in experimentally infected rabbits.^{21,32} Pretreatment of sera with pronase, which presumably disrupts immune complexes and nonspecific protein binding to the fungal capsule, increased the sensitivity of the antigen detection test. In a cat with nasal infection caused by *T. pullulans*, cryptococcal antigen test findings of serum were negative before clinical evidence of dissemination.¹⁰

Polymerase chain reaction has been used to develop genus-specific primers for detection of *Trichosporon* spp. in clinical specimens and culture.^{27,30} Pathogenic *Trichosporon* sp. can be detected with this method, while DNA sequences of other similar pathogenic yeasts such as *Malassezia* spp., *Candida* spp., and *C. neoformans* are not amplified.

66.5 PATHOLOGIC FINDINGS

Histologic findings in trichosporonosis are similar to those of disseminated aspergillosis and consist of abscesses and nodular infarcts, with mycotic vascular invasion, thrombosis, and infiltration of neutrophils and macrophages.³ Spherical to oval yeastlike organisms (blastoconidia), 3 to 8 μ m in diameter, arthroconidia, and septate hyphae can be seen in tissue sections and impression smears ([Figs. 66-2](#) and [66-3](#)). In disseminated lesions, fungal elements often proliferate from a central nidus to produce a radial or sunburst pattern of growth ([Figs. 66-4](#)

Infectious Diseases of the Dog and Cat, 3rd Edition

and 66-5). All fungal elements are readily stained with periodic acid-Schiff and Gomori's methenamine silver stains as a result of abundant polysaccharides in the fungal cell walls. The arthroconidia, formed by hyperseparation and disarticulation of hyphal segments, are frequently difficult to demonstrate in tissue sections. When this problem occurs, *Trichosporon* spp. and *Candida* spp. can be mistaken for each other and must be distinguished by immunohistologic or cultural studies.¹⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

66.6 THERAPY

In general, *Trichosporon* spp. are more susceptible in vitro to benzimidazole compounds than they are to amphotericin B (AMB) or flucytosine. Resistance can vary among particular pathogenic species. Multifocal cutaneous *T. asahii* infection in a person was treated successfully with liposomal AMB and fluconazole in combination.³⁵ AMB has been effective in treating disseminated infection in an infant.³⁶ Resistance to AMB often has been demonstrated when treating infected people,³⁴ but itraconazole (ITZ) has been effective.¹ Multiple drug-resistant *Trichosporon* spp. from people have been susceptible to voriconazole.^{5, 6} Caspofungin has also been used to treat drug-resistant *Trichosporon* infections in people.¹⁸ See Drug Formulary, [Appendix 8](#), for further information on these novel antifungal drugs. Cats should initially be treated orally with ITZ when antifungal susceptibility data is not available ([Table 66-1](#)). Cats that develop anorexia, vomiting, or diarrhea may need to have the dosage reduced to 50 mg total on alternate days. ITZ is not as hepatotoxic in cats as is ketoconazole (KTZ). Reduction of ITZ dosage has been associated with relapse of disease. Surgical removal of a nasal granuloma in one cat with *T. pullulans* infection was incomplete, and later dissemination occurred despite treatment with KTZ or AMB and flucytosine.¹⁰

b Dose per administration at specified interval.

c May have to extend therapy based on response.

66.7 PUBLIC HEALTH CONSIDERATIONS

No documented zoonotic risk of *Trichosporon* infections exists in animals. These yeasts are ubiquitous in the environment and on the mucosa of clinically healthy animals and people; however, they can proliferate to large numbers in the lesions of affected animals. Contamination of human skin and mucosal surfaces is possible when handling infected animals. Transmission of infection in a dairy between cows was suspected via the handlers and the milking equipment or other fomites. Therefore wearing of gloves and hand washing is important to prevent colonization of people working in a contaminated environment.

67 CHAPTER 67 Miscellaneous Fungal Infections

Amy M. Grooters

Carol S. Foil

Infections caused by miscellaneous fungal and pseudofungal pathogens include pythiosis and lagenidiosis, which are caused by aquatic pathogens in the class Oomycetes and several opportunistic fungal infections that affect dogs and cats sporadically. Although identification of specific fungal pathogens is usually impossible without culture, these infections can often be categorized to some degree on the basis of their morphologic features, such as pigmentation, hyphal diameter, and septation in tissue. Infections caused by opportunistic fungi are generally classified by the form of the fungal elements in tissue and whether they are pigmented; for example, phaeohyphomycosis is caused by pigmented hyphal forms, hyalohyphomycosis by unpigmented hyphal forms, and eumycotic mycetoma by fibrosing granuloma with sulfur grains containing pigmented or unpigmented fungal elements. The diseases and agents are summarized in [Table 67-1](#).

Clinically, distinguishing these infections is important because of differences in epidemiology, treatment, and prognosis. Therefore uncultured lesions should not be classified by pathologic features without the aid of serology, the polymerase chain reaction (PCR), or immunohistochemistry. In addition, diagnosis of any infection caused by a saprophytic fungus must be made on the basis of isolation of the organism from tissue (not exudate) and histologic evidence of tissue invasion by a morphologically compatible organism.

Pythiosis, lagenidiosis, and zygomycosis are caused by a taxonomically diverse group of pathogens but share similar clinical and histologic characteristics; all cause lesions characterized by pyogranulomatous and eosinophilic inflammation associated with broad, sparsely septate hyphae. Because of these similarities, they were previously grouped together in the category of *phycomycosis*. Although phycomycosis is a convenient label for cases in which a definitive culture-based diagnosis has not been made, the term is no longer an appropriate taxonomic designation and should be replaced in current literature with the more specific terms *pythiosis*, *lagenidiosis*, and *zygomycosis*. The obsolete term “chromomycosis” occasionally still appears in the veterinary literature as a synonym for either phaeohyphomycosis or chromoblastomycosis, the latter of which has not yet been described in animals.¹⁵ Another difficulty for clinicians is the confusion that arises from taxonomic revisions in medical mycology, which results in confusing synonymy in fungal nomenclature. Excellent resources for updated fungal nomenclature can be found in the literature²⁴ and online at www.doctorfungus.org.

67.1 PYTHIOSIS

Pythiosis is best known as a cause of gastrointestinal (GI) or cutaneous disease in dogs^{29,89} and of cutaneous granulomas in horses.¹⁸ It has also been described as an uncommon cause of cutaneous or subcutaneous lesions in cats^{9,25,40,121} and calves⁹¹ and of arteritis, keratitis, or periorbital cellulitis in people.^{4,61,113,122}

67.1.1 Etiology

*Pythium insidiosum*²² is an aquatic pathogen belonging to the class Oomycetes in the kingdom Stramenopila (Chromista). *Pythium* species and other oomycetes differ from true fungi in producing motile, flagellate zoospores and having cell walls that contain cellulose and β -glucan but not chitin. In addition, ergosterol is not an important component of the oomycete cell membrane. Furthermore, members of the genera *Pythium* and

Infectious Diseases of the Dog and Cat, 3rd Edition

Lagenidium are sterol auxotrophs—they incorporate sterols from their environment rather than producing them. Other members of the genus *Pythium* are plant pathogens of some economic importance. Based on molecular studies, the pathogens most closely related to oomycetes are the *Prototheca* species.⁶⁷ The infective stage of *P. insidiosum* is thought to be the biflagellate aquatic zoospore, which is released into warm water environments and likely causes infection by encysting in damaged skin or GI mucosa.⁴⁰ Although the specific factors that favor sporulation of *P. insidiosum* in the environment are unknown, some evidence suggests that certain types of plant material may be involved in the life cycle as a natural host.⁸⁸

67.1.2 Epidemiology

In the United States, pythiosis is encountered most often in the Gulf Coast states but has been recognized with some frequency in animals living as far north as New Jersey, Virginia, Kentucky,⁸¹ southern Illinois, and southern Indiana and as far west as Oklahoma, Missouri, and Kansas. Surprisingly, during the past 2 years, GI pythiosis was confirmed in several dogs that lived in Arizona but had not traveled outside the Southwest.⁴¹ In addition, in fall 2003, GI pythiosis was confirmed in two dogs living in northern California.⁵¹ Globally, pythiosis is most often encountered in Southeast Asia (especially Thailand and Indonesia), eastern coastal Australia, New Zealand, and South America but has also been recognized in Korea, Japan, and the Caribbean.

Pythiosis is most often identified in young, large-breed male dogs and is especially common in outdoor working breeds such as Labrador retrievers.²⁸ Affected dogs are taken to the veterinarian more often in the fall, winter, and early spring than in the late spring and summer months.⁸⁹ In cats, specific breed and sex predilections have not been apparent in the few cases that have been reported. However, of 11 cats with cutaneous pythiosis diagnosed through the authors' laboratory since 1999, six were younger than 10 months old, with an age range of 4 months to 9 years.⁴²

Infected dogs often have a history of recurrent exposure to warm, freshwater habitats. However, some infections develop in suburban house dogs with no known access to a standing body of water. Because *P. insidiosum* zoospores have been shown to have an affinity for damaged skin,⁸³ it would make sense to assume that animals with cutaneous wounds or parasite-induced injury to GI mucosa are more likely to become infected. However, solid epidemiologic evidence to support this assumption is lacking. Other risk factors for the development of pythiosis have not been identified. Affected animals are typically immunocompetent and otherwise healthy.

67.1.3 Clinical Findings

Clinical signs caused by *P. insidiosum* infection are the result of cutaneous or GI lesions or of disease extension into adjacent tissues or regional lymph nodes. Cutaneous and GI lesions are rarely found together in the same patient. Systemic dissemination of pythiosis has only been described once.²⁹

Cutaneous pythiosis in small animals typically causes nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts (Figs. 67-1 and 67-2).^{29,121} Affected dogs are usually taken to the veterinarian because of solitary or multiple cutaneous or subcutaneous lesions involving the extremities, tailhead, ventral neck, perineum, or medial thigh. When present, regional lymphadenomegaly often reflects extension of infection rather than just reactive inflammation. Lesions in 11 cats with cutaneous pythiosis recently evaluated through the authors' laboratory have included subcutaneous masses (some of which were highly invasive) in the inguinal, tailhead, or periorbital regions, and draining nodular lesions or ulcerated plaquelike lesions on the extremities (see Fig. 67-1), occasionally centered on the digits or footpad. Two cats with pythiosis had large subcutaneous masses affecting the extremities and cranioventral thorax but no cutaneous involvement.¹²¹ In a third case, *P. insidiosum* infection resulted in nasal cavity and nasopharyngeal lesions and bilateral retrobulbar masses.⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 67-2 Cutaneous pythiosis in dog. Split-thickness graft was performed after resection of subcutaneous pythiosis lesion and became infiltrated with new granulomatous nodules. Leg was amputated, curing the disease. (Courtesy Carol Foil, Louisiana State University, Baton Rouge, La.)

Infectious Diseases of the Dog and Cat, 3rd Edition

GI pythiosis in dogs is characterized by severe segmental transmural thickening of the stomach, small intestine, colon, rectum, or (although rarely) the esophagus or pharyngeal region (Fig. 67-3).^{28,54,89,99} Mesenteric lymphadenomegaly is common and occasionally observed without accompanying GI tract lesions. The gastric outflow area, duodenum, and ileocolic junction are the most frequently affected portions of the GI tract, and it is not uncommon to find two or more segmental lesions in the same patient. Inflammation in affected regions is typically centered on the submucosa, with variable mucosal ulceration and occasional extension of disease through serosal surfaces, resulting in adhesion formation and peritonitis. Involvement of the mesenteric root may cause severe enlargement of mesenteric lymph nodes, which are often embedded in a single, large, firm granulomatous mass that is palpable in the midabdomen. Extension of disease into mesenteric vessels may result in bowel ischemia, infarction, perforation, or acute hemoabdomen.¹⁰⁰ In addition, infection may extend from the GI tract into contiguous tissues such as the pancreas and uterus.^{28,89} In one report, a prostatic abscess caused by *P. insidiosum* was observed in a dog with an adjacent colonic lesion.⁶² Clinical signs associated with GI pythiosis include weight loss, vomiting, diarrhea, hematochezia, or all of these symptoms. Physical examination often reveals a very thin body and a palpable abdominal mass. Signs of systemic illness such as lethargy or depression are not typically present unless intestinal obstruction, infarction, or perforation occurs. Similar to clinical signs observed in dogs, those of GI pythiosis in cats have been attributed to partial intestinal obstruction, palpable abdominal masses, and mesenteric lymphadenomegaly.^{101a}

67.1.4 Diagnosis

The definitive diagnosis of pythiosis has traditionally been challenging because histologic features are not specific and culture is often not performed successfully. However, numerous highly specific serologic, immunohistochemical, and molecular-based tools for the diagnosis of pythiosis have been developed. These assays are likely to make the definitive diagnosis of pythiosis possible in the majority of affected animals, even when culture is unsuccessful. In addition, they may provide clinicians with an opportunity to make a diagnosis earlier in the course of disease, when lesions may be more amenable to surgical or medical therapy.

67.1.4.1 Culture

Isolation of *P. insidiosum* from infected tissues is not difficult when appropriate sample handling and culture techniques are used. For best results, unrefrigerated tissue samples should be wrapped in a sterile saline-moistened gauze sponge, shipped at ambient temperature, and arrive at the laboratory within 24 hours of collection. However, when samples cannot be processed for more than 2 to 3 days after collection, they should be shipped with ice packs, stored in the refrigerator, or stored at ambient temperature in an antibiotic solution to decrease proliferation of bacterial contaminants.⁵⁰ The use of selective media significantly increases the likelihood of isolating pathogenic oomycetes. The authors routinely use vegetable extract agar⁵⁰ amended with streptomycin (200 µg/ml) and ampicillin (100 µg/ml) for the isolation of *P. insidiosum*. As a commercially available alternative, Campy blood agar (Remel, Inc., Lenexa, Kan.), which contains

Infectious Diseases of the Dog and Cat, 3rd Edition

trimethoprim, vancomycin, polymyxin B, cephalothin, and amphotericin B (AMB), is also effective. Small pieces of fresh, nonmacerated tissue should be placed directly on the surface of the agar and incubated at 37° C (98.6° F); growth is typically observed within 12 to 24 hours.

Although the identification of oomycetes is generally based on morphologic features of sexual reproductive structures such as oogonia and antheridia, isolates of *P. insidiosum* rarely produce these structures in vitro. Therefore identification of *P. insidiosum* should be based on colonial and hyphal characteristics; growth at 37° C; production of motile, reniform, biflagellate zoospores; and if possible, specific PCR amplification or ribosomal RNA (rRNA) gene sequencing. Colonies on vegetable extract, Sabouraud's dextrose, or cornmeal agar are typically submerged, are white to colorless, and have an irregular radiate pattern.^{7,23} Microscopically, hyphae are broad (4 to 10 µm in diameter), hyaline, sparsely septate, and tend to branch at right angles. Zoospores can be readily produced by placing boiled grass blades on the surface of a 1- to 2-day-old colony growing on 2% water agar, incubating at 37° C for 18 to 24 hours, and then placing the infected grass blades in a dilute salt solution.^{19,35,86} After 2 to 4 hours of incubation at 37° C, terminal vesicles from which zoospores are released can be seen extending from the cut edges of the infected grass blades. Although the production of zoospores is an important supporting feature for the identification of pathogenic oomycetes, it is not specific for *P. insidiosum*.

67.1.4.2 Serology

Immunoblot analysis has been used successfully to demonstrate the ability of sera from *Pythium*-infected horses,⁸⁵ dogs,⁶⁶ and cats^{101a} to recognize antigens of *P. insidiosum* and has the added advantage of high specificity and sensitivity. Because of these advantages, immunoblot analysis is currently the authors' serologic test of choice for evaluation of dogs and cats suspected of having pythiosis, lagenidiosis, or zygomycosis. In addition, a soluble mycelial antigen-based enzyme-linked immunosorbent assay (ELISA) for the detection of anti-*P. insidiosum* antibodies in dogs and cats has been found to be highly sensitive and specific for the diagnosis of pythiosis.⁴⁷ In addition to providing a means for early, noninvasive diagnosis, the ELISA also appears to be useful for monitoring response to therapy in affected patients. In 11 dogs and 2 cats assessed through the authors' laboratory, a dramatic decrease in antibody levels approaching the range of healthy animals was detected 2 to 3 months after successful surgical resection of infected tissues. In contrast, antibody levels remain high in animals that have a clinical recurrence after surgical treatment. Therefore the ELISA appears to be a promising tool for the early detection of postoperative recurrence and may also be used to guide the duration of postoperative medical therapy.

67.1.4.3 Molecular Assays

To circumvent the difficulties associated with obtaining a culture-based diagnosis of pythiosis, a *P. insidiosum*-specific PCR assay was recently developed.⁴³ This assay can be applied to DNA extracted either from cultured isolates or appropriately preserved infected tissue samples.¹²⁶ In addition, this technique has been successfully used with DNA extracted from paraffin-embedded tissues sections.⁶² The major advantage of this assay is its high specificity.

67.1.4.4 Immunohistochemistry

Immunohistochemical techniques based on polyclonal antibodies developed first by Brown et al¹³ and later by Newton⁹⁹ have been used regularly during the past 10 years as confirmatory tests for pythiosis. An

Infectious Diseases of the Dog and Cat, 3rd Edition

advantage of these techniques is that they can be used with paraffin-embedded tissues, permitting the evaluation of archival samples. However, at least one of these antibodies has demonstrated cross-reactive staining when used to evaluate tissues from dogs with conidiobolomycosis⁵⁸ and lagenidiosis.⁴⁶ Therefore the specificity of this antibody for the immunohistochemical diagnosis of pythiosis may be questionable. A new polyclonal anti-*P. insidiosum* antibody raised in chickens and adsorbed with sonicated *Lagenidium* and *Conidiobolus* hyphae appears to be highly specific for the immunohistochemical detection of *P. insidiosum* hyphae in tissues.⁴⁹

641

67.1.5

Pathologic Findings

642

A presumptive diagnosis of pythiosis, lagenidiosis, or zygomycosis can occasionally be established cytologically if lesions are accessible (Fig. 67-4). Cytologic examination of exudate from draining tracts, impression smears made from ulcerated skin lesions, and fine needle aspirates of enlarged lymph nodes often reveal pyogranulomatous, suppurative, or eosinophilic inflammation (or all of these). In addition, macerated tissue fixed in 10% potassium hydroxide (KOH) may be examined microscopically for the presence of typical wide, poorly septate, branching hyphal elements.

Histologic findings associated with pythiosis are characterized by eosinophilic granulomatous to pyogranulomatous inflammation with fibrosis. Affected tissues typically contain multiple foci of necrosis surrounded and infiltrated by neutrophils, eosinophils, and macrophages. In addition, discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and fewer neutrophils and eosinophils may be observed.^{28,29,59} Vasculitis is occasionally present. Organisms are usually found within areas of necrosis or at the center of discrete granulomas.⁸⁹ Although *P. insidiosum* hyphae are difficult to visualize on sections stained with hematoxylin-eosin (H and E) stain, they may be identified as clear spaces (*hyphal ghosts*) surrounded by a narrow band of eosinophilic material.⁸⁹ Hyphae are easily visualized in sections stained with Gomori's methenamine silver (GMS) but not with periodic acid-Schiff (PAS). They are broad (mean, 4 μ m; range, 2 to 7 μ m), rarely septate, and occasionally branching.^{29,89}

Cutaneous pythiosis typically causes severe nodular to diffuse ulcerative dermatitis and panniculitis. Because areas of inflammation are most often found in the deep dermis and subcutis, wedge biopsies are preferred to punch biopsies when pythiosis is suspected. Similarly, because inflammation in GI pythiosis centers on the submucosal and muscular layers rather than mucosa and lamina propria,⁸⁹ the diagnosis of pythiosis may be missed on endoscopic biopsies that fail to reach deeper tissues. Therefore pythiosis should be considered as a differential diagnosis when endoscopic biopsies reveal eosinophilic or pyogranulomatous inflammation without identification of an etiologic agent.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 67-2 Drug Therapy for Miscellaneous Fungal Infections^a

DRUG ^b	SPECIES	DOSE (MG/KG) ^c	ROUTE	INTERVAL	DURATION (MONTHS)
Itraconazole ^d	B	10 ^e	PO	24 hr	3–9
	B	5–15 ^f	PO	24 hr	3–9
Terbinafine ^d	D	5–10 ^e	PO	24 hr	3–9
Amphotericin B lipid complex (ABLC)	D	2–3 ^g	IV	3 times weekly	
Amphotericin B lipid complex (ABLC)	C	1 ^h	IV	3 times weekly	

\B, Dog and cat; D, dog; C, cat; PO, by mouth; IV, intravenous.

a Including pythiosis, lagenidiosis, zygomycosis, hyalohyphomycosis, and phaeohyphomycosis.

b See [Appendix 8](#), Drug Formulary, for more information on these drugs.

c Dose per administration at specified interval.

d Combination of itraconazole and terbinafine recommended for treatment of pythiosis and lagenidiosis.

e Recommended dose for pythiosis and lagenidiosis.

f Recommended dose for zygomycosis, phaeohyphomycosis, and hyalohyphomycosis.

g For a cumulative dose of 24 to 27 mg/kg.

h For a cumulative dose of 12 mg/kg.

67.1.6 Therapy

Aggressive surgical resection is the treatment of choice for pythiosis. Because it provides the best opportunity for a long-term cure, complete excision of infected tissue should be pursued whenever possible. When cutaneous lesions are limited to a single distal extremity, amputation is recommended. In animals with GI pythiosis, segmental lesions should be resected with 3- to 4-cm margins whenever possible. Despite the fact that mesenteric lymphadenomegaly is almost always present, *P. insidiosum* hyphae are often absent in enlarged mesenteric nodes. Therefore the presence of nonresectable mesenteric lymphadenomegaly should not dissuade the surgeon from pursuing complete resection of a segmental bowel lesion. In this situation, enlarged lymph nodes should be biopsied and cultured for prognostic information. Unfortunately, most dogs with GI pythiosis are not taken to the veterinarian until late in the course of disease, when complete excision is not possible. In addition, the anatomic location of the lesion may prevent complete surgical excision when the esophagus, gastric outflow tract, rectum, or mesenteric root is involved.

Local postoperative recurrence of pythiosis is common and can occur either at the site of resection or in regional lymph nodes. For this reason, combination medical therapy with itraconazole (ITZ) and terbinafine is recommended for at least 2 to 3 months after surgery ([Table 67-2](#)). To monitor for recurrence, ELISA serology should be performed before and 2 to 3 months after surgery. In animals that have had a complete surgical resection and do not have a recurrence of disease, serum antibody levels drop significantly within 3 months of surgery.⁴⁷ If this occurs, medical therapy can be discontinued, with subsequent reevaluation of serum antibody levels in 3 months. If antibody levels remain elevated 2 to 3 months after surgery, medical therapy should be continued, with periodic reevaluation of ELISA serology.

Infectious Diseases of the Dog and Cat, 3rd Edition

Medical therapy for pythiosis has traditionally been unrewarding, likely because ergosterol (the target for most currently available antifungal drugs) is generally lacking in the oomycete cell membrane. Despite this fact, clinical and serologic cures have been obtained using medical therapy with ergosterol-targeting drugs in a small number of *P. insidiosum*-infected dogs, as well as with an infection in a 2-year-old child.¹¹³ In the authors' experience during the past 5 years at Louisiana State University, a small number of dogs with GI pythiosis have responded to either ITZ or amphotericin B (AMB) lipid complex (see Table 67-2). More recently, the authors have observed clinical and serologic improvement or resolution in several cases of canine and feline cutaneous pythiosis treated with the combination of ITZ and terbinafine. Although the percentage of animals responding is still low (less than 20%), based on our subjective observations, the combination protocol seems superior to ITZ or AMB alone.

642

643

Caspofungin, the first antifungal in the newly developed echinocandin class of β -glucan synthase inhibitors to gain United States Food and Drug Administration approval, has the potential to be a much more effective drug for the treatment of oomycosis because of the large amount of β -glucan present in the oomycete cell wall. However, it is extremely costly and likely to be used only on rare occasions.

A vaccine derived from soluble mycelial antigens and secreted exoantigens of *P. insidiosum* has been used successfully to treat cutaneous granulomas in horses and vasculitis in people.^{60,120} Unfortunately, although controlled trials have not been completed, the efficacy of *Pythium* vaccines in dogs appears to be poor, and clinical improvement has not been observed in any of the authors' patients.

The limited published information currently available regarding the efficacy of *Pythium* vaccines in dogs is anecdotal.⁸⁴ In one canine case report that suggested a vaccine-related therapeutic effect,⁵⁶ tissues were submitted to Louisiana State University that were obtained after the initial diagnostic wedge biopsies but before vaccine administration. The tissue culture was negative for oomycetes and failed to show any hyphae in multiple GMS-stained sections, suggesting that the disease may have been resolving before the vaccine administration.³⁹ Interestingly, the authors of this chapter are aware of one additional dog in which lesions associated with cutaneous pythiosis resolved completely without additional therapy after incomplete surgical resection.

67.1.7 Public Health Considerations

Infections caused by *P. insidiosum* are acquired from the environment. No evidence suggests transmission between hosts; however, routine precautions should be taken when handling infected tissues or exudates.

67.2 LAGENIDIOSIS

Until recently, *P. insidiosum* was considered to be the only mammalian pathogen in the class Oomycetes. However, in 1999 a second pathogenic oomycete was isolated from tissue taken from a dog with severe multifocal cutaneous lesions and regional lymphadenomegaly. The dog died acutely after rupture of a caudal vena caval aneurysm, and necropsy revealed severe sublumbar lymphadenitis and pyogranulomatous vasculitis. Sequencing of a portion of the rRNA gene of the isolate recovered from this dog identified it as member of the genus *Lagenidium*.⁴⁵ More than 40 dogs with serologic, histologic, or culture evidence (or all of these) of *Lagenidium* species infection have been identified.

Infectious Diseases of the Dog and Cat, 3rd Edition

67.2.1 Etiology

The majority of species in the genus *Lagenidium* are parasites that infect algae, fungi, rotifers, nematodes, crustaceans, *Daphne*, and insect larvae. The best studied species, *Lagenidium giganteum*, is a larval mosquito pathogen approved by the United States Environmental Protection Agency for use as a biocontrol agent for mosquitos.⁶⁴ Although antigenic and molecular similarities suggest that the canine pathogenic *Lagenidium* species is closely related to *L. giganteum*, differences in their in vitro growth characteristics and the failure of *L. giganteum* to infect rodents in mammalian safety studies⁶³ suggest that they are likely distinct species. Little is known about the life cycle of the canine pathogenic *Lagenidium* species, although it is likely similar to that of *P. insidiosum* and *L. giganteum*.

67.2.2 Epidemiology

The epidemiologic and clinicopathologic features of lagenidiosis that have thus far been identified are similar in many respects to those that have previously been associated with cutaneous pythiosis. Affected animals are typically young to middle-age dogs living in the southeastern United States. Although most of these dogs have been from Florida or Louisiana, dogs in Texas, Tennessee, Virginia, and Indiana have been identified as well. Numerous infected dogs frequented lakes or ponds. Two of the dogs were unrelated housemates,⁴⁶ suggesting that environmental exposure to the pathogen may play an important role in infection.

67.2.3 Clinical Findings

Dogs with lagenidiosis are typically taken to the veterinarian with progressive cutaneous or subcutaneous lesions (often multifocal) involving the extremities, mammary region, perineum, or trunk.⁴⁶ Grossly, these lesions appear as firm dermal or subcutaneous nodules or as ulcerated, thickened, edematous areas with regions of necrosis and numerous draining tracts (Fig. 67-5). Regional lymphadenomegaly is often noted and may develop in the absence of cutaneous lesions. Animals with great vessel or sublumbar lymph node involvement often develop hind limb edema. Similar to the clinical course associated with cutaneous pythiosis, skin lesions in dogs with lagenidiosis tend to be progressive, locally invasive, and poorly responsive to therapy. However, in contrast to pythiosis the majority of dogs with lagenidiosis have been found to have lesions in distant sites, including great vessels, sublumbar and inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum. Lagenidiosis has not been identified in cats.

643

644

Fig 67-5 Ulcerative dermatitis caused by *Lagenidium* species infection in young dog with progressive multifocal skin lesions and generalized lymphadenopathy. (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, La.)

67.2.4 Diagnosis

Immunoblot serology for the detection of anti-*Lagenidium* antibodies in canine serum can provide a presumptive diagnosis of lagenidiosis, but must be interpreted in conjunction with results of serologic testing for *P. insidiosum* infection because of the potential for cross-reactivity in serum from dogs with pythiosis.⁴⁶ A definitive diagnosis of lagenidiosis is best made by culture. Isolation techniques for *Lagenidium* species are similar to those described for *P. insidiosum* but involve peptone-yeast-glucose (PYG) agar amended with ampicillin (100 µg/ml) and streptomycin (200 µg/ml).

Infectious Diseases of the Dog and Cat, 3rd Edition

Identifying *Lagenidium* isolates based on morphologic characteristics is more difficult than identifying *P. insidiosum* because zoospores are only occasionally produced with the techniques used for sporulation of *P. insidiosum* and because sexual reproductive structures have not been identified. Colonies of *Lagenidium* species on PYG agar are submerged and white to colorless. Microscopically, mature hyphae are broad (25 to 40 μm in diameter), are occasionally to frequently branching or budding, and often appear as segmented chains of rectangular to oval structures in mature colonies. Because of the current limitations associated with morphologic characterization of this pathogen, definitive identification of *Lagenidium* species should be based on rRNA gene sequencing or specific PCR amplification.³⁹ The same PCR assay can also be used to detect *Lagenidium* DNA in infected tissue samples.¹²⁶

67.2.5 Pathologic Findings

The histologic features of lagenidiosis, which are similar to those associated with pythiosis and zygomycosis, are characterized by pyogranulomatous and eosinophilic inflammation associated with broad, irregularly branching, sparsely septate hyphae. In contrast to *P. insidiosum*, *Lagenidium* species hyphae are usually visible on sections stained with H and E. On GMS-stained sections, numerous broad, thick-walled, irregularly septate hyphae are easily recognized (Fig. 67-6). *Lagenidium* hyphae typically vary significantly in size but in general are much larger than *P. insidiosum* hyphae, ranging from 7 to 25 μm in diameter, with an average of 12 μm .⁴⁶ Cytologic examination of lymph node aspirates or exudate from draining tracts may reveal pyogranulomatous to eosinophilic inflammation with or without broad, poorly septate hyphal elements.⁴⁰

67.2.6 Therapy

Aggressive surgical resection of infected tissues is the treatment of choice for lagenidiosis. In animals with lesions limited to a single distal extremity, amputation is recommended. In those with cutaneous or subcutaneous lesions in other areas of the body, the surgeon should pursue aggressive resection with wide margins. Because dogs with lagenidiosis often have occult systemic lesions, radiographic imaging of the chest and abdomen and sonographic imaging of the abdomen are recommended to determine the extent of disease before attempting surgical resection of cutaneous lesions. Unfortunately, the majority of *Lagenidium*-infected dogs have nonresectable disease in regional lymph nodes or distant sites by the time the initial diagnosis is made. Medical therapy for lagenidiosis is typically ineffective. However, a combination of ITZ with terbinafine combined with aggressive surgical resection was effective in resolving a *Lagenidium* species infection in two dogs with multifocal cutaneous lesions but no systemic lesions (see Table 67-2). In general, the prognosis for dogs with lagenidiosis is grave.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 67-6 Broad, thick-walled, irregularly septate hyphae associated with granulomatous vasculitis in lymph node from 2-year-old dog with *Lagenidium* species infection (GMS stain). (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, La.)

67.2.7 Public Health Considerations

Infections caused by *Lagenidium* species are acquired from the environment. No evidence suggests transmission between hosts; however, routine precautions should be taken when handling infected tissues or exudates.

67.3 ZYGOMYCOSIS

The term *zygomycosis* refers to infections caused by fungi in the class Zygomycetes, including the genera *Basidiobolus* and *Conidiobolus* in the order Entomophthorales, and the genera *Rhizopus*, *Absidia*, *Mucor*, *Saksena*, and others in the order Mucorales. In humans and veterinary patients, the Mucorales organisms tend to cause an acute, rapidly progressive disease in debilitated or immunocompromised individuals, whereas the Entomophthorales organisms typically cause chronic localized infections in subcutaneous tissue or nasal submucosa of immunocompetent patients.¹⁰⁸ Culture-confirmed infections caused by pathogens in the order Mucorales have not been well documented in small animals. However, in dogs, *Basidiobolus* and *Conidiobolus* species have been reported to cause cutaneous pyogranulomatous lesions that are grossly and histologically similar to those caused by *P. insidiosum* and *Lagenidium* species.

67.3.1 Etiology and Epidemiology

Basidiobolus ranarum (previously *Basidiobolus haptosporus*), *Conidiobolus coronatus*, *Conidiobolus incongruus*, and *Conidiobolus lamprauges* are saprophytes that are widely distributed in nature. *Conidiobolus*

Infectious Diseases of the Dog and Cat, 3rd Edition

and *Basidiobolus* species are found in soil and decaying plant matter, and *Basidiobolus* species are also commonly isolated from insects and the feces of amphibians and reptiles.¹⁰⁸ Cutaneous infection with *Basidiobolus* or *Conidiobolus* species likely occurs by percutaneous inoculation of spores through a minor trauma or insect bites. Dogs with hard palate lesions caused by *Conidiobolus* species may become infected by direct implantation of spores when chewing on decaying pieces of wood. Infection may also result from inhalation or ingestion of spores. Affected animals are typically immunocompetent.

644

645

67.3.2

Clinical Findings

In humans, horses, sheep, and other mammalian species, conidiobolomycosis is usually a nasopharyngeal infection with possible local dissemination into tissues of the face, retropharyngeal region, and retrobulbar space. In two dogs evaluated by the authors, a presumptive diagnosis of nasopharyngeal conidiobolomycosis was made on the basis of histologic and serologic findings. One of the dogs showed signs of chronic nasal cavity disease, and the other had a severe chronic ulcerative dermatitis of the nasal planum. In two other dogs evaluated in the authors' hospital, culture-confirmed conidiobolomycosis was associated with ulcerative lesions of the hard palate (Fig. 67-7). Both dogs had radiographically apparent involvement of the nasal cavity or nasopharynx. In a fifth dog described in the literature, *Conidiobolus* infection was associated with multifocal nodular draining subcutaneous lesions and regional lymphadenomegaly. In addition, a *Conidiobolus* species was recently confirmed as the cause of pneumonia in a dog that was receiving chemotherapy for treatment of lymphoma.⁴⁴ Culture-confirmed cases of zygomycosis in cats have not been well described. However, the authors have made a presumptive diagnosis of conidiobolomycosis based on histopathology and serology in a 3-year-old cat with an ulcerative lesion of the hard palate.

Basidiobolomycosis is a rare cause of ulcerative draining skin lesions in dogs (Fig. 67-8) and in one case was reported as a cause of tracheobronchitis.³⁸ Disseminated *Basidiobolus* species infection involving the GI tract and other abdominal organs have been described in two dogs.^{88,92} In addition, the authors have evaluated samples from two dogs (one with a focal preputial lesion and another with a focal vulvar lesion) in which a presumptive diagnosis of basidiobolomycosis was made on the basis of histologic and serologic findings. Complete surgical resection of the infected tissue cured both animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

67.3.3 Diagnosis

Because serologic and immunohistochemical techniques are not currently available for the diagnosis of conidiobolomycosis and basidiobolomycosis in small animals, a definitive diagnosis must be based on isolation and identification of the pathogen. Entomophthorales organisms typically grow well on media routinely used for the isolation of pathogenic fungi, such as Sabouraud's dextrose agar, potato flakes agar,¹⁰⁹ potato dextrose agar, or cornmeal agar. The authors routinely use potato flakes agar amended with ampicillin (100 µg/ml) and streptomycin (200 µg/ml) for initial isolation of *Conidiobolus* and *Basidiobolus* species.

Identification of zygomycetes in the laboratory is generally based on morphologic characteristics of asexual reproductive structures (conidia) and sexual reproductive structures (zygospores).²⁴ *Conidiobolus* isolates on potato flakes agar or half-strength cornmeal agar readily produce primary conidia that are forcibly discharged and can be visualized on the underside of the petri dish lid. Primary conidia of *C. coronatus* are spherical, 40 µm in diameter and have a prominent basal papilla. Because *C. coronatus* is a heterothallic species, zygospores are not observed in clinical isolates. However, *C. incongruus* is a homothallic species that produces large (15- to 25-µm), round, smooth, thick-walled zygospores without beaks. Reproductive structures of *B. ranarum* are readily produced after 3 to 5 days of incubation on half-strength cornmeal agar. Zygospores are easily identified as large (20- to 50-µm), thick-walled, round intercalary structures with beaklike protuberances that represent the remains of copulatory tubes. Primary conidia (often with a hyphal tag still attached), secondary conidia (morphologically similar to primary conidia but often smaller), and capilliconidia (oval to elongate spores with a terminal adhesive knob that develop at the end of a thin supporting hypha) may all be seen on the inside of the petri dish lid.

Fig 67-8 Dog with multifocal cutaneous and subcutaneous draining lesions caused by *B. ranarum* infection. Notice resemblance of this lesion to lesion caused by *P. insidiosum* (see Fig. 67-2). (Courtesy University of Georgia, Athens, Ga.)

645

Fig 67-9 *Conidiobolus* species hyphae in tissue biopsy from ulcerative hard palate lesion in 3-year-old female boxer. Note large amount of amorphous eosinophilic material (sleeve) surrounding the hyphal segment (H and E stain). (Courtesy Amy Grooters, Louisiana State University, Baton Rouge, La.)

67.3.4 Pathologic Findings

The histologic features of zygomycosis are similar to those associated with pythiosis and lagenidiosis. On GMS-stained sections, hyphae appear broad, thin-walled, and occasionally septate. The histologic hallmark of zygomycosis is the presence of a wide (2.5- to 25- μ m) eosinophilic sleeve surrounding the hyphae and making them easily located on sections stained with H and E (Fig. 67-9). This finding helps to differentiate zygomycosis from pythiosis and lagenidiosis, in which eosinophilic sleeves tend to be thin or absent. In addition, the hyphal diameter tends to be significantly larger for *Basidiobolus* species (mean, 9 μ m; range, 5 to 20 μ m) and *Conidiobolus* species (mean, 8 μ m; range, 5 to 13 μ m) than for *P. insidiosum* (mean, 4 μ m; range, 2 to 7 μ m).⁹⁰

67.3.5 Therapy

Recommendations for the treatment of zygomycosis are not straightforward because attempted therapy has only been described in a few patients with culture-confirmed diagnoses. Although anecdotal information and a small number of cases in the literature suggest that cutaneous zygomycosis may be less aggressive than cutaneous pythiosis or lagenidiosis, progression of lesions and occasionally even dissemination despite treatment have also been described in zygomycete-infected dogs. This may reflect variability in the susceptibility of *Conidiobolus* and *Basidiobolus* isolates, as suggested by results of in vitro susceptibility testing performed in a limited number of isolates.¹²⁵ The most appropriate recommendation for the treatment of zygomycosis in small animal patients is aggressive surgical resection of infected tissues when possible, followed by ITZ therapy for 2

Infectious Diseases of the Dog and Cat, 3rd Edition

to 3 months (see [Table 67-2](#)). If resection is not possible, therapy with either ITZ or AMB lipid complex should be recommended.

67.3.6 Public Health Considerations

Zygomycetes are saprophytic and acquired from the environment. They are not transmitted directly between hosts.

67.4 HYALOPHYPHOMYCOSIS

Hyalohyphomycoses are opportunistic infections caused by nondematiaceous fungi that form hyphal elements in tissue. By convention, aspergillosis and penicilliosis are not included (see [Chapter 64](#)). Cases of hyalohyphomycosis described in dogs or cats are summarized in [Table 67-1](#).

67.4.1 Etiology

In animals and humans, at least 50 species of fungus classified in more than 20 genera in 3 phyla (Deuteromycota, Ascomycota, and Basidiomycota) have been implicated as agents in hyalohyphomycosis.⁷⁷ An unidentified species of *Acremonium* has been associated with disseminated disease¹¹⁶ and multifocal subcutaneous disease.³⁷ *Acremonium hyalinulum* has been associated with osteomyelitis and nephritis,⁵² and *Acremonium kiliense* has been associated with keratoconjunctivitis in dogs.⁸² A *Fusarium* species was the cause of an unilateral pyelonephritis²² and an undocumented case of disseminated disease in Australian dogs. *Fusarium solani* was isolated from an ear lesion of a cat.²¹ *Geotrichum candidum* infection has been reported in disseminated diseases¹⁰⁷ and in infections after bite wounds; it has also been reported as a cause of cutaneous nodules¹⁰³ and superficial dermatitis¹¹⁴ in dogs and as a cause of disease in cats.

Paecilomyces fumosoroseus, *Paecilomyces variotii*, *Paecilomyces lilacinus*, and other *Paecilomyces* species⁹⁶ have been associated with cutaneous and disseminated lesions in dogs and cats.^{30, 98, 123} Hypercalcemia, as with other granulomatous diseases, has been associated with disseminated infection.⁷³ *Pseudallescheria* (which is also called *Allescheria*, *Petriellidium*, and *Scedosporium apiospermum*) *boydii* has been isolated from dogs with pneumonia and from dogs with osteomyelitis and disseminated disease.^{5, 110, 123}

The fungi that cause hyalohyphomycosis are generally ubiquitous soil saprophytic molds and are common contaminants of laboratory cultures. *P. lilacinus* is found in tap water and contaminates “sterile” solutions. *Fusarium* species have been found in water systems in human hospitals, a source of infection that has been responsible for many nosocomial infections in immunocompromised people.² *Geotrichum* species may also be considered a normal part of the oral and GI flora.⁶⁸ Unfortunately, in some reported cases the identification of invasive infection in animals and humans as being caused by *Geotrichum* is questionable.⁶⁸ *P. boydii*, which is a much more common cause of hyalohyphomycosis in people than the other causative agents, causes disparate syndromes, especially in those who are immunocompromised, including sinusitis, keratitis, brain abscess, arthritis, fungal ball, endocarditis, cutaneous disease, and disseminated disease. Similar clinical localizations have been observed in infected dogs.¹⁴ *Metarhizium anisopliae* was the cause of rhinitis in a cat.⁹⁵ *Trichoderma* species have been recognized as an emerging cause of infection in people²⁰; however, they have not yet been documented in dogs and cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

Although saprophytic fungi are considered opportunistic infectious agents in local or disseminated disease in dogs and cats, rarely is an associated predisposing condition identified. In particular, *Fusarium* infections are associated with neutropenia in humans, and *P. boydii* is associated with neutropenia and human immunodeficiency virus (HIV) infection⁷⁷; these types of associations have not yet been made for companion animals. However, a tendency for saprophytic fungi to infect German shepherd dogs¹²³ and dissemination after treatment with glucocorticoids¹⁰⁷ have been noted.

67.4.2 Clinical Findings

Clinical features that characterize the individual infections are difficult to generalize because so few cases have been reported. *Geotrichum* species in particular and *Paecilomyces* species may colonize epithelial surfaces and thus be more likely to begin as local disease after wounding or to remain confined to skin or mucosae.

646

647

However, for each species, reports of disseminated disease have been made and can result from immunosuppression caused by terminal illness, immunosuppressive drugs, or long-term antibiotic usage. Dissemination is apparently hematogenous. Signs vary with the organ system affected, which can be the nasal passages, sinuses, lungs, central nervous system (CNS), myocardium, bone and bone marrow, lymph nodes, spleen, kidneys, liver, peritoneum, and pleura. Pneumonia has been prominent in dogs with disseminated geotrichosis.¹⁰⁷ One case of unilateral pyelonephritis with local extension into the retroperitoneal space was associated with a *Fusarium* species.²² Some cases of cutaneous and subcutaneous nodules have been reported, both of which may be localized or widespread. *Acremonium*, *Fusarium*, and *Pseudallescheria* organisms have been reported as causes of canine keratomycosis.^{75,117}

67.4.3 Diagnosis and Pathologic Findings

Many potentially pathogenic fungi that cause hyalohyphomycosis are common laboratory contaminants. Furthermore, most can frequently be isolated from the skin and hair coats of clinically healthy animals. Mycology laboratories frequently have problems identifying members of this group of fungi, which is unfortunate because species-specific treatment guidelines have been developed in human medicine for the fungal agents.¹¹⁹ PCR-based identification is available for *Pseudallescheria* species, the fungi most often implicated in human disease.¹²⁴ Documentation of invasive disease involves cultural and histologic correlation. Evidence of tissue invasion and morphologic characteristics compatible with a fungus isolated from cultures properly obtained from clinical specimens renders the most definitive diagnosis (see [Figs. 56-13](#) and [56-14](#)). Specimens should not be contaminated with epithelial flora or obtained from open wounds. When appropriate specimens are not obtained for fungal culture or when histologic specimens are the only material available, many pathogenic fungal species can be tentatively identified with immunohistochemical techniques. However, in the United States, this type of testing is generally obtainable only by referring the specimens to the Centers for Disease Control and Prevention (CDC) in Atlanta, Ga.

67.4.4 Therapy

Animals with disseminated or CNS disease have a grave prognosis. In many reported cases, treatment has been attempted with AMB or imidazoles (see [Table 67-2](#)). Many reports have described treatment with ITZ in particular. In a report of disseminated paecilomycosis in a dog, the initial positive response to combined flucytosine (FCY) and fluconazole therapy was followed by recurrence and death.⁹⁶ Temporary remission was

Infectious Diseases of the Dog and Cat, 3rd Edition

also observed after treatment with ketoconazole (KTZ) in a dog with disseminated *Paecilomyces* infection.¹⁰ In some cases, treatment seems to prolong the survival of dogs with disseminated disease,^{73,116,123} but few dogs have been reported to survive disseminated hyalohyphomycosis. If treatment is attempted, the isolate should be identified and subjected to in vitro susceptibility testing to formulate a rational therapeutic plan.^{78,119} In humans with keratitis or a deep infection with *Pseudallescheria boydii*, combination therapy with AMB and antifungal azoles is recommended.⁷⁷ When disease is localized, surgical removal is the treatment of choice, although dissemination might be expected. Keratitis is often treated with topical natamycin or miconazole. When treating *Paecilomyces* infections, it is important to note that its various species have apparently widely differing drug susceptibilities. *P. varioti* is reportedly sensitive to AMB and FCY, whereas *P. lilacinus* is resistant to them but sensitive to imidazoles and even griseofulvin.¹⁷ A cat with invasive *M. anisopliae* rhinitis improved after treatment with ITZ; however, the animal had a relapse after therapy was discontinued.⁹⁵

67.4.5 Public Health Considerations

The fungi that cause hyalohyphomycosis are mostly saprophytic and acquired from the environment. They are not transmitted directly between hosts.

67.5 PHAEOHYPHOMYCOSIS

67.5.1 Etiology and Epidemiology

Phaeohyphomycoses are uncommon opportunistic infections caused by numerous ubiquitous saprophytic and plant pathogenic molds. They form characteristic pigmented (dematiaceous) hyphal elements in tissue. The pigment is melanin, and the fungus may be very pale to very dark, generally staining with Masson-Fontana melanin in histologic sections. The presence of melanin in their cell walls may be their virulence factor. Taxonomy of the commonly implicated agents is confusing, and the generic names change frequently. Fungi classified as Deuteromycetes, which belong to more than 100 species and 60 genera, have been described as agents of phaeohyphomycosis in animals or humans.⁷⁷ The number of reports about these types of infections in humans and animals is increasing.^{105,106,115} These fungi are thought to be one of the major emerging groups of pathogenic fungi in laboratory diagnoses.³³

Hyphae in phaeohyphomycosis differ from those associated with most hyalohyphomycoses by their thick walls, varying diameters, and yeastlike swellings. Phaeohyphomycosis differs from the human disease chromoblastomycosis in that the spherical yeastlike bodies do not have septa in two perpendicular planes like the sclerotic bodies of the chromoblastomycosis infection. Phaeohyphomycosis is also different from dark-grain mycetomas, which are discussed in the following section. All of the infections caused by pigmented fungi are often called *chromomycoses*.

The organisms that have been isolated from canine and feline phaeohyphomycotic infections are listed in [Table 67-1](#).

Alternaria, *Bipolaris*, *Exophiala*, *Phialemonium*, *Phialophora*, and *Stemphyllium* species are ubiquitous wood and soil saprophytes. Interestingly, *Exophiala* organisms and other dematiaceous fungi may be easily isolated from oligotrophic water sources such as hospital water supplies, sauna facilities, and bathroom drain pipes.^{76,97} *Moniliella* organisms have been recovered from cheese, butter, and margarine. *Ochroconis* species are usually a

Infectious Diseases of the Dog and Cat, 3rd Edition

cause of phaeohyphomycosis in cold-blooded vertebrates. Several of the potentially pathogenic species have been cultured from the skin of clinically healthy people, cats, and dogs.^{16,36,93,94} Animals and people presumably are exposed to infection with dematiaceous fungi by wound contamination, especially through wood splinters, although initial respiratory tract colonization cannot be ruled out in systemic cases. The route of exposure in cerebral phaeohyphomycosis is not understood, although extension from sinus infections, orbital injuries, and middle ear infections has been postulated as a route in humans. *Bipolaris* species are usually associated with paranasal sinus infections in humans,⁷⁷ and rhinitis has been described in a cat.⁸⁷ Some species of *Cladophialophora* demonstrate neurotropism.^{3,74}

Only rarely are cases of localized phaeohyphomycosis in animals associated with other systemic disorders or obvious immunosuppression. These infections are not associated with HIV-induced immunosuppression in humans; however, central venous catheters have been implicated in some cases.⁷¹ Intact granulocyte function is an important defense mechanism against these infectious agents.⁷⁷ Persistent lymphopenia has been either a cause or an effect of infection in dogs with systemic infections.⁷² Hyperglobulinemia can occur as a result of a persistent but an ineffective humoral response. Of the reported cases, one dog was treated with long courses of glucocorticoids, one dog had ehrlichiosis, one cat had leukemia, and another cat was treated with glucocorticoids. All of these immunosuppressed patients had disseminated phaeohyphomycosis.

67.5.2 Clinical Findings

67.5.2.1 Subcutaneous and Dermal Phaeohyphomycosis

Singular or multifocal, poorly circumscribed, and ulcerating or fistulating nodules and plaques characterize subcutaneous and dermal phaeohyphomycosis (Figs. 67-10 and 67-11). The fungal pigmentation is often apparent in the tissue (Fig. 67-12). In cats the lesions may resemble chronic bacterial abscesses or thick-walled cysts, which may evolve over weeks to months. In dogs, cutaneous lesions have been associated with osteomyelitis. In a report of a dog with phaeohyphomycosis caused by *Curvularia geniculatum*, the lesions had a sporotrichoid appearance involving lymphatics and lymph nodes on the affected limb.⁶ In one report of disseminated cutaneous infection with *Curvularia* species in a dog that had been treated with glucocorticoids, organisms were seen histopathologically within hair follicles and furunculosis lesions.⁵⁷ The authors speculated that the hair follicle could be a route of infection in a dog without a penetrating skin wound.

Fig 67-10 Cutaneous phaeohyphomycosis on pinna of cat with ulcerated and crusted nodule. Lesion was pigmented clinically and on cut surface. Disease was resolved by routine excisional biopsy. (Courtesy Carol Foil, Louisiana State University, Baton Rouge, La.)

Fig 67-11 Extensive cutaneous ulceration caused by subcutaneous phaeohyphomycosis caused by *Bipolaris spicifera*. (Courtesy Kenneth Kwochka, The Ohio State University, Columbus, Ohio.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Most cases of subcutaneous and dermal phaeohyphomycosis have been described in cats, and lesions in this species most often occur on the face or distal extremities. *Bipolaris spicifera*, *Exophiala jeanselmei*, and *Phialophora verrucosa* are the most common isolates. *Alternaria alternata*, *Cladophialophora bantiana*—which usually causes cerebral phaeohyphomycosis—and *Fonsecaea pedrosoi*—the agent most often implicated in human chromoblastomycosis—have been associated with nasal dermal nodules in cats.^{1,31,79}

67.5.2.2 Cerebral (Encephalitic or Brain Abscess) Phaeohyphomycosis

The agents involved in cerebral phaeohyphomycosis are almost always *Cladophialophora* (formerly *Cladosporium*, *Xylohypha*) species (Fig. 67-13). Authors of a recent case report of a cat tentatively identified a new agent, *Phoma eupyrena*.⁷⁰ Dogs and cats are both affected.^{11,32,74} CNS disease can also develop as a manifestation of disseminated phaeohyphomycosis. Neurologic dysfunction varies with the site of disease, because most cases involve localized brain abscesses.

Keratomycosis in a cat has been associated with *Cladophialophora* species and in dogs with *Alternaria* and *Curvularia* species. A recent report of intraocular granulomatous uveitis in a cat is the first published instance of intraocular phaeohyphomycosis.⁸

67.5.2.3 Disseminated Phaeohyphomycosis

Systemic phaeohyphomycosis usually has an acute to subacute course, with symptoms varying according to the organ system involved. As noted, CNS disease is prominent and invariably fatal, and some patients have potentially immunosuppressive conditions. A report of disseminated *C. bantiana* in a Maltese dog with ehrlichiosis is an example.¹¹¹ In addition a report of disseminated *Phialemonium obovatum* in a German shepherd dog was associated with depressed lymphocyte blastogenesis.¹¹⁸ In contrast, there is a report of multifocal disease caused by *E. jeanselmei* in a 14-year-old spayed domestic short-haired cat had no known immunosuppressive condition.⁵⁵ Multifocal lesions in this cat were detected ultrasonographically in the liver and kidneys. On necropsy, multifocal granuloma-like masses were seen on the liver, kidneys, abdominal wall, mesentery, thoracic wall, pericardium, and epicardium. Similar lesions were found on the cervical portion of the spinal cord, cerebrum, and cerebellum.

Infectious Diseases of the Dog and Cat, 3rd Edition

67.5.3 Diagnosis

Direct examination of exudate or macerated tissue mounted in KOH may reveal the pigmented fungal elements. As with other opportunistic mycoses, confirmation of the diagnosis is based on the concomitant demonstration of hyphae in tissue and culture of a morphologically compatible organism from properly obtained tissue specimens. Histopathologically, dematiaceous fungi may appear darkly pigmented or need to be visualized using special lighting, processing techniques, or stains to demonstrate the presence of melanin in the fungal elements.¹⁰² These organisms grow readily on Sabouraud's dextrose agar, although specialized agar may be required to encourage production of the identifying fruiting bodies (see [Fig. 56-12](#)). Regardless, some expertise is required for specific mycologic identification,³³ and a referral to a specialized laboratory such as the Fungus Testing Laboratory at the University of Texas Health Science Center in San Antonio, Tex., may be required (see [Appendix 5](#), Laboratory Testing for Infectious Disease). When culture cannot be obtained, specific identification of the most commonly pathogenic species may be performed with experimental immunohistochemical techniques available at the CDC.

CNS lesions may be investigated with magnetic resonance imaging, computerized tomographic (CT) imaging, and cerebrospinal fluid analysis. In one report of stereotactic CT-guided biopsy of a brain lesion in a dog caused by *C. bantiana*, a tentative diagnosis was obtained cytologically from a smear preparation of the material, a histologic diagnosis was made, and the organism was obtained in culture for specific diagnosis.³

67.5.4 Therapy

An animal with disseminated CNS disease or widespread cutaneous disease has a grave prognosis. Successful treatment of the localized cutaneous forms often seen in cats has been described (see [Table 67-2](#)). When the lesions are excisable, surgery may be curative,⁷⁹ but recurrence at the same or new sites is common.

In animals with unexcisable lesions or recurrent disease, antifungal chemotherapy may be helpful, but the response is unpredictable. Drugs should be chosen on the basis of in vitro sensitivity and susceptibility testing if possible; the imidazoles have variable in vitro activity against saprophytic organisms. A cat apparently was cured after multiple excisions and treatment with KTZ,⁸⁷ and yet another was treated successfully with AMB and FCY.⁸⁰ In other feline cases, treatment with both KTZ and FCY was unsuccessful.⁶⁵ In a published report a dog with disseminated cutaneous infection with *Phialemonium curvatum* was cured long term with KTZ at 5 mg/kg/day (2.3 mg/lb/day).¹² ITZ treatment of human subcutaneous and musculoskeletal phaeohyphomycosis has been reviewed¹¹²; of 17 patients assessed, only 3 were cured, although another 6 improved. In all cases the fungal isolates were reported to be susceptible to ITZ on in vitro testing. A cat with granulomatous rhinitis caused by *E. jeanselmei* was successfully treated with oral ITZ given for 30 days. Another cat with *Fonsecaea* nasal granuloma responded to 4- to 6-month courses of ITZ at 5 mg/kg (2.3 mg/lb) every 12 hours but relapsed 6 to 9 months after cessation of treatment each time.³¹ Terbinafine, an allylamine, has been shown to be useful in some people with phaeohyphomycosis.^{27,101}

67.5.5 Public Health Considerations

The fungi that cause phaeohyphomycosis are mostly saprophytic and acquired from the environment. They are not transmitted directly between hosts.

Infectious Diseases of the Dog and Cat, 3rd Edition

67.6 EUMYCOTIC MYCETOMAS

Mycetomas are pyogranulomatous nodules that contain tissue grains or granules. The grains contain dense colonies of organisms and host-derived matter—usually necrotic debris.

67.6.1 Etiology

When mycetomas are caused by fungi, they are classified as *eumycotic mycetomas* to distinguish them from *actinomycotic* lesions (see [Chapter 49](#)) and *botryomycosis*, a bacterial pseudomycosis caused by organisms such as staphylococci. Eumycotic mycetomas must also be differentiated from the pseudomycetomas seen in long-haired cats with generalized dermatophytosis (see [Chapter 58](#)).

Eumycotic mycetomas may be caused by fungi that impart their pigmented appearance to the grains in tissue; they are called *black-grain*, or *dark-grain*, *mycetomas*. Black-grain mycetomas have been associated with infections by *Curvularia* species, *Madurella* species, and *Staphylotrichum coccosporum*. Unpigmented organisms cause white-grain mycetomas. White-grain mycetomas have been caused by *Acremonium* and *Pseudallescheria* species. Most eumycotic mycetomas are confined to the subcutaneous tissues, but white-grain mycetomas on the body wall may be extensions of abdominal cavity disease. Fungal isolation from affected dogs and cats has not been done in all cases. Of the black-grain mycetomas, *Curvularia geniculata* is the most common isolate, and infections caused by *Curvularia spicifera*, *Curvularia lunata*,²⁶ and *Curvularia senegalensis*²¹ have been reported. In abdominal and body wall white-grain mycetomas of the dog, *P. boydii* and *A. hyalinum* have been isolated. Disseminated infection was caused by *Acremonium* species in a dog.¹¹⁶ *Madurella grisea* has been isolated from a cat with mycetoma, and *Madurella mycetomatis* has been isolated from a dog.⁶⁹ A cat positive for feline leukemia virus was reported to have simultaneous dermatophytic pseudomycetoma and subcutaneous black-grain mycetomas caused by an agent not previously reported to be pathogenic—*Staphylotrichum coccosporum*.³⁴

649

650

67.6.2 Clinical Findings

In white-grain mycetomas, most infections have involved abdominal cavity organs. Dogs have developed peritonitis or abdominal masses after contamination from unrelated surgical wound dehiscence. As with aspergillosis, German shepherd dogs have the greatest prevalence rate of infection. Peritonitis and intraabdominal granulomas accompanied by symptoms typical of septic peritonitis are noted. Lesions within the abdomen have tissue grains and are usually caused by *P. boydii*. Systemic infection caused by *Acremonium* was characterized by signs of neurologic dysfunction, uveitis, and visceral granulomas.¹¹⁶ A black-grain mycetoma caused by *M. mycetomatis* developed at the site of a uterine stump subsequent to wound dehiscence after ovariectomy.⁶⁹

Cutaneous mycetoma has been the typical finding of black-grain infection. Infection probably develops at the site of a superficial wound, possibly contaminated by a plant foreign body. Such cases are more often reported in dogs than in cats and are most often caused by *Curvularia* species. In one cat, a black mycetoma developed after a bite wound. Lesions are cutaneous nodules, relatively poorly circumscribed, and usually on the extremities or the face. They do not often ulcerate widely, but fistulas may form within the nodule. Most become surmounted by alopecic and hyperkeratotic epidermis. Cycles of healing and ulceration may lead to firm swelling and scarring. Black tissue grains may be visible within the exudate, or the exudate or the tissue

Infectious Diseases of the Dog and Cat, 3rd Edition

itself may appear black. Some nodules are so heavily pigmented that they are mistaken for cutaneous melanomas. On the limbs and feet, the infectious process may involve underlying bone.

67.6.3 Diagnosis and Pathologic Findings

A presumptive diagnosis of mycetoma can be made if grains are found within exudate from any draining tract. Cytologic investigation must be directed at the tissue grains, because organisms are often scant or absent elsewhere within exudates or tissues. Grains may be crushed and smeared on a slide for staining in some cases. Black grains are often gritty and may require digestion in 10% KOH before they can be mounted for microscopic study. The fungal elements are usually quite evident in thinly smeared or flattened grains. Serum may be tested for specific antibodies by agar gel immunodiffusion. In histologic specimens, common fungi may be identified by immunohistochemical techniques.

Investigation by culture technique is otherwise necessary to confirm cytologic findings and identify the causative organism. Tissue grains may be collected from exudate and washed in sterile saline for culturing. Alternatively, if surgically excised tissue contains grains, it can be cultured. Fungal isolates should be retained for possible in vitro sensitivity and susceptibility testing. The agents associated with mycetomas in dogs and cats are readily cultured on standard media.

67.6.4 Therapy

The prognosis in abdominal mycetoma is guarded, because patients described to date have had extensive involvement of abdominal organs, have not responded to debridement, chemotherapy, or both. Cutaneous mycetoma is not a life-threatening disease but is difficult to resolve. Radical surgical excision is the treatment most often used for humans. Amputation of affected limbs may be necessary; spontaneous resolution does not occur. Any attempt at antifungal chemotherapy should be based on in vitro susceptibility testing of the isolate. Even if an antifungal chemotherapeutic agent that may be helpful is identified, it is apparently difficult to attain effective levels within the tissue grains where the organism resides. Successful outcomes have been reported in humans with local hyperthermia treatments and improvement with high-dose ITZ.¹⁰⁴ Scattered reports have been made of successful treatment of mycetomas in people with terbinafine with or without other agents.⁵³

67.6.5 Public Health Considerations

The fungi that cause eumycotic mycetomas are saprophytic and acquired from the environment. They are not transmitted directly between hosts.

68 CHAPTER 68 Pneumocystosis

Craig E. Greene

Francis M. Chandler

Remo Lobetti

68.1 ETIOLOGY

Pneumocystis carinii, the etiologic agent of pneumocystosis, occurs worldwide and infects virtually all mammalian species, including people. A saprophyte of low virulence, *Pneumocystis* spp. exist in temperate and tropical climates at altitudes up to 5000 feet. Its primary habitat is the mammalian lung where it causes opportunistic infection. Estimates of latent human infections range from 1% to 10% of the population. Subclinical or latent infections are common in rats, mice, guinea pigs, rabbits, cats, sheep, and various wild animals. Clinical pneumonia has been reported to occur spontaneously in dogs, pigs, horses, goats, nonhuman primates, and people. Airborne transmission is suspected because healthy animals become infected when they are housed with infected animals.⁶ The presumption is that the organism may have a yet undiscovered dormant life stage in the environment. Most reports of clinical *P. carinii* pneumonia are linked with documented or suspected cell-mediated immunodeficiency in the host. Rarely, *P. carinii* disseminates to extrapulmonary sites.

The taxonomy of *P. carinii* is uncertain. It has been classified using freeze-fracture techniques as a unicellular protozoan belonging to the phylum Sarcomastigophora, subphylum Sarcodina. Ultrastructurally, the reproductive behavior of *P. carinii* is similar to the ascospore formation of yeast cells, and its organelles and staining properties by light microscopy resemble those of most pathogenic fungi. Phylogenetic classification based on 16S-like rRNA sequences indicates that *P. carinii* is most closely related to the fungi of the class Ascomycetes, especially *Saccharomyces cerevisiae*. Biologically, however, it behaves similar to a protozoan and is sensitive to drugs used to treat sporozoan infections but resistant to most antifungal drugs. The morphology of the organisms and the histopathology of the lesions produced by both human and animal isolates throughout the world are similar. Only a single species name had been assigned to the genus *Pneumocystis*, but antigenic differences suggest that several strains may exist. Biologic differences between isolates from different hosts are suggested by the relative difficulty of experimental interspecies transmission. Although controversial, the designated species infecting people, known previously as *P. carinii* f. sp. *hominis*, is now named *Pneumocystis jiroveci*.^{30,51} The species found in the rat continues to be called *P. carinii*. Species designations for the organisms isolated from dogs and other animals will require further genetic and biologic study. For purposes of this chapter, and with few exceptions listed later in this text, the organism infecting dogs and people will continue to be labeled *P. carinii*.

68.2 EPIDEMIOLOGY

P. carinii appears to be maintained in nature by transmission from infected to susceptible animals within a species. Although spore collections suggest an environmental source, none has been determined. The primary mode of spread is thought to be airborne droplet transmission between hosts. The contagious nature of pneumocystosis is suggested by the epidemic spread that has occurred in institutionalized people. Sporadic case reports may represent an activation of latent infection by stress, crowding, and immunosuppressive therapy during hospitalization of latent carriers. Clinical disease has also been experimentally activated after glucocorticoid therapy, cytotoxic chemotherapy, and irradiation of laboratory rodents. A higher prevalence of infection has been

Infectious Diseases of the Dog and Cat, 3rd Edition

found in dogs with canine distemper compared with a corresponding control population.⁵² However, genetic analysis of isolates in people indicate that most infections are not acquired early in life but rather result from an infected source that is likely of the same species within a given geographic region.⁷ Therefore recent acquisition of infection, rather than reactivation of infection, may be responsible for clinical illness.³⁵ The greater prevalence of pneumocystosis is probably caused not only by an increased awareness of it, but also by the increased use of immunosuppressive therapy.

The entire life cycle of *P. carinii* is completed within the alveolar spaces where organisms adhere in clusters to the lining cells. Ultrastructural studies have contributed a large body of information concerning the life cycle of *P. carinii* (Fig. 68-1). Two main forms, the trophozoite (1–4 μ) and cyst (8 μ m), are found there. Although *Pneumocystis* infections are usually confined to the lungs, in human cases and an infection in one dog, organisms have been reported in extrapulmonary sites. Causes of severe cell-mediated immunodeficiency in humans, such as acquired immunodeficiency syndrome (AIDS), can be associated with lymphatic or hematogenous dissemination of organisms from the lungs to other tissues. Transmission of infection to an offspring can occur via aspiration of contaminated amniotic fluid from placental infection.

68.3 PATHOGENESIS

Pneumocystis can be inhaled from the environment and then can colonize the lower respiratory tract of clinically healthy mammals. *Pneumocystis* organisms rarely multiply to large numbers in the lungs of clinically healthy hosts. In conditions in which impaired host resistance (especially reduced CD4 T-lymphocyte counts) or preexisting pulmonary disease is present, rapid proliferation of organisms can occur. The overgrowth and clustering of *P. carinii* within alveolar spaces can then lead to alveolocapillary blockage and decreased gaseous exchange. Intraalveolar organisms are often accompanied by thickening of alveolar septa, but they seldom invade the pulmonary interstitium and are rarely phagocytosed by alveolar macrophages. With an adequate immune response, the body may eliminate the infection, but the removal of large numbers of organisms and cellular debris may take up to 8 weeks. Organisms and the minimal inflammatory response they provoke contribute to the pulmonary alveolar damage.

In infected people, when extrapulmonary pneumocystosis occurs, it is rare and occurs primarily when accompanied by overwhelming pulmonary infection, profound underlying immunodeficiency, and long-term use of aerosolized pentamidine for prophylaxis against *P. carinii* pneumonia in human immunodeficiency virus (HIV)-infected individuals.⁵⁷ Sites of extrapulmonary infection include lymph nodes, spleen, liver, bone marrow, gastrointestinal tract, eyes, thyroid gland, adrenal glands, kidneys, heart, pancreas, and external auditory canal.

651

652

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 68-1 Haploid trophozoites replicate asexually by mitosis (A) and also conjugate to form a precyst (B). The cyst undergoes meiosis and subsequent mitosis eventually producing a mature cyst containing eight haploid organisms (C). The cyst matures and finally ruptures releasing the ovoid- or crescent-shaped trophozoites (D). As the process continues, the once open alveolus (E) becomes filled obstructing ventilation (F). See Figure 68-10 for more detailed view of E and F. (Courtesy University of Georgia, Athens, Ga.)

68.4 CLINICAL FINDINGS

68.4.1 Cats

In general, pneumocystic infections of cats are latent or subclinical, as they are in people. The organism has been found in the lungs of cats, but clinical disease has not been reported. Lung specimens examined from cats suffering from feline leukemia virus infection, interstitial pneumonia, or both have not shown evidence of pneumocystosis. Cats that were experimentally infected with *P. carinii* isolated from mice developed a cough, tachypnea, and pneumonia if they were immunosuppressed with concurrent glucocorticoid administration.⁵⁸ In contrast, subclinical infections occurred in cats that did not receive immunosuppressive therapy.

Infectious Diseases of the Dog and Cat, 3rd Edition

68.4.2 Dogs

Most canine cases have been in miniature dachshunds younger than 1 year with a suspected congenital immunodeficiency,^{36,38} although cases of pneumocystosis have been reported in a Shetland sheepdog and Yorkshire terrier,¹¹ as well as in adult Cavalier King Charles spaniels.^{10,13,45,53} The syndrome of common variable immunodeficiency (CVID) in which B cells produce little or no antibody in association with normal or reduced B-cell numbers has been suspected to occur in affected miniature dachshunds.³⁶ Immunologic studies on these dogs showed hypogammaglobulinemia; deficiency of serum IgA, IgG, and IgM; decreased lymphocyte transformation response to phytohemagglutinin and pokeweed mitogens; and absence of B lymphocytes with presence of T lymphocytes in the lymphoid tissue stained with CD3 and CD79a lymphocyte markers. Immunoglobulin deficiencies have also been observed in affected Cavalier King Charles spaniels.⁵⁶

The clinical features of pneumocystic pneumonia in dogs are similar to those caused by other pulmonary pathogens except for dry lung sounds, nonproductive cough, and low-grade or absent fever. The typical clinical history is that of gradual weight loss and respiratory difficulty progressing over 1 to 4 weeks (Fig. 68-2). The weight loss, which occurs in spite of a good appetite in most dogs, may be associated with diarrhea and occasional vomiting. Coughing is not always reported, but reduced exercise tolerance is uniform. Infected animals have responded minimally or temporarily to antibiotic and glucocorticoid therapy.

Abnormalities on physical examination include dyspnea, tachycardia, and increased dry respiratory sounds on thoracic auscultation. Animals are usually in poor condition, cachectic, and may show dermatologic changes, such as superficial bacterial pyoderma and demodicosis. Although the mucous membranes are generally of normal color, they may be cyanotic in severely affected animals. Affected dogs remain relatively alert and afebrile, although slight (1° to 2° C [1.8° to 3.6° F]) elevations of rectal temperature have been reported. Fluid may be present in the thoracic and peritoneal cavities of some dogs. Ocular fundic lesions known as “cotton wool spots” rarely occur in people with pneumocystosis, and they represent infarction of the nerve fiber layer. They have not been reported in animal infections.

652

653

Infectious Diseases of the Dog and Cat, 3rd Edition

68.5 DIAGNOSIS

Hematologic abnormalities are usually nonspecific, and a neutrophilic leukocytosis with a shift suggesting inflammation is seen most consistently. Less frequently, eosinophilia and monocytosis are found. Polycythemia may occur secondarily to arterial hypoxemia from impaired gaseous exchange. Thrombocytopenia, which can be significant enough to cause bleeding, has been a complication in people. In contrast, thrombocytosis may be present in miniature dachshunds. Artifactual thrombocytopenia and megathrombocytosis has been observed in Cavalier King Charles spaniels³; however, this finding has a hereditary basis likely unrelated to the suspected immunodeficiency. Biochemical alterations are usually nonspecific. Total serum proteins are usually within reference limits with a low to borderline-low globulin level, which correlates with low γ -globulin levels on serum protein electrophoresis.³⁸ Low globulin levels and decreased lymphocyte function have been reported in a Cavalier King Charles spaniel.²⁶ Low levels of IgA, IgG, and IgM have been apparent. Arterial hypoxemia (oxygen tension [PO_2] at or below 80), hypocapnia (carbon dioxide tension [PCO_2] at or below 35), and increased arterial blood pH indicate an uncompensated respiratory alkalosis. The PO_2 is often lower than would be expected from the clinical signs and thoracic radiographs.

Findings on thoracic radiography include diffuse, bilaterally symmetric, miliary-interstitial to alveolar lung disease (Fig. 68-3), with compensatory emphysema in severely infected animals. Solitary lesions, unilateral involvement, cavitary lesions, spontaneous pneumothorax, and lobar infiltrates are occasionally present. Tracheal elevation, right-sided heart enlargement, and pulmonary arterial enlargement reflect cor pulmonale secondary to diffuse pulmonary disease.

Fig 68-3 Lateral survey thoracic radiograph from a dog with pneumocystosis showing a diffuse miliary interstitial density. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

For detecting human infections, serologic tests have been developed, but their diagnostic value is uncertain. Unfortunately, many immunodeficient patients who develop pneumocystosis fail to produce antibody titers, and healthy contacts of these patients frequently have higher titers than the patients themselves. Increased antibody titers to *P. carinii* persist for long periods, offering a valuable index of infection in epidemiologic studies. However, they are of limited use for an immediate diagnosis. An increase in titer over 2 to 3 weeks is needed to confirm active infection. Circulating *Pneumocystis* antigen has been detected in human serum by counterimmunoelectrophoresis and enzyme-linked immunosorbent assay (ELISA) methods. However, antigenemia also is found in up to 15% of clinically normal people who have been tested.

P. carinii has been successfully propagated in cell cultures but not on a continual basis. Immunosuppressed rodents have been used to propagate organisms for serologic and experimental testing. Because of the difficulty of isolation of organisms, diagnosis requires direct demonstration of *P. carinii* in biopsy specimens, respiratory fluids, or occasional extrapulmonary sites. Sputum, transtracheal or endotracheal washings, gastric contents, and oropharyngeal secretions may contain organisms. Transtracheal aspirates have been effective for identifying organisms in dogs.³⁸ Samples for cytology may be obtained by endobronchial brushing and transbronchoscopic biopsy, but these procedures require special endoscopic equipment and involve the risks of general anesthesia. Transtracheal or endotracheal lavage and percutaneous transthoracic needle aspiration are more available to practitioners and have been shown to have good correlation with transbronchoscopic biopsy findings in confirming a diagnosis. None of the cytologic techniques are as reliable or as definitive as is histopathologic examination of lung biopsy specimens for documenting active pneumocystosis. Lung biopsy is unfortunately more invasive, has potential complications of hemorrhage or pneumothorax, and is associated with additional costs and hospitalization.

653

Of 24 reported cases in dogs reported in the literature, diagnosis was made antemortem in 15 dogs. When premortem diagnosis was attempted, multiple procedures were often used. Tracheal washing was performed in nine dogs, and the organism was found in seven dogs by one group of investigators.^{32,38} Bronchoalveolar lavage results were positive in one of the two cases in which it was used.^{45,53} Transthoracic needle aspiration was performed in three dogs; two developed pneumothorax, and one died as a direct result of the procedure.^{21,45} The aspirate was diagnostic in only one of the dogs. Unfortunately, endoscopic or percutaneous lung biopsy has the greatest risk of complications. Hemorrhage, secondary infection, pneumothorax, and death from anesthesia have been reported after biopsy in dogs. Open surgical biopsy is the preferred method and gives a definitive diagnosis.^{3,21} The least traumatic and invasive method involves a laparotomy with a transdiaphragmatic approach.³ Antimicrobial therapy can begin 24 to 48 hours before specimen collection in a patient suspected of having pneumocystosis, without the drug masking the presence of organisms in the sample.

654

To facilitate early diagnosis and treatment, impression smears for cytologic study should be made from all tissues before fixation for histologic evaluation. The cytologic material obtained is placed on a glass microscope slide to dry, after which it is selectively stained with methenamine silver for cysts or with Giemsa for nuclei of intracystic sporozoites and trophozoites (Figs. 68-4 and 68-5). Diff-Quik (a modified Giemsa stain) can be used as a fast and inexpensive screening stain after which negative results can be confirmed with more sensitive staining.¹⁷ Unfortunately, *Pneumocystis* organisms are difficult to detect in respiratory secretions or washing, and success in finding them usually depends on the experience of the examiner and the collection and processing of specimens. Direct or indirect fluorescent antibody (FA) test has been effective in specifically detecting organisms in sputum, tracheal aspirates, or pulmonary tissue (Fig. 68-6).⁴³ Immunoperoxidase techniques also can be used to identify *P. carinii* in impression smears and in formalin-fixed, paraffin-embedded lung sections (Fig. 68-7, A and B).³⁴ Polymerase chain reaction (PCR) has been effective in the detection of *P. carinii* in bronchoalveolar lavage

Infectious Diseases of the Dog and Cat, 3rd Edition

specimens from people^{33,35,39,46} and in lung tissue from dogs.^{26,53} Sensitivity of PCR on bronchoalveolar lavage fluids from infected people has been greater than that of conventional staining without loss of specificity.²² DNA analysis of *Pneumocystis* isolates has been used for epidemiologic monitoring of isolates from people and animals.²⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

68.6 PATHOLOGIC FINDINGS

Pathologic findings in pneumocystosis are primarily confined to the lungs, although dissemination to regional lymph nodes, spleen, liver, bone marrow, and other organs has been reported. On gross examination, the lungs are firm, consolidated, and pale brown or gray (Fig. 68-8). They do not collapse when the chest cavity is opened. Unlike in many pneumonic processes, fluid is not expressed from cut surfaces of the lung. The pulmonary and mediastinal lymph nodes are often enlarged. Despite the apparent lack of pleural inflammation, small amounts of fluid may be found in the pleural cavity. Cardiac enlargement, when present, has been right sided in all cases.

Appropriate histologic staining is essential to ensure detection of *P. carinii* organisms (Table 68-1). The routine hematoxylin and eosin stain does not readily demonstrate the developmental forms of *P. carinii*, which may explain why the disease is not recognized more frequently (Fig. 68-9). With this stain, only the hematoxylinophilic nuclei of intracystic sporozoites and trophozoites are demonstrated. Various modifications of methenamine silver staining can be employed to stain the cyst walls brownish-black, but trophozoites will not be detected (Fig. 68-10). Overstaining with Gomori's methenamine silver (GMS) may cause blackened and crenated erythrocytes in alveolar spaces to be mistaken for cyst forms of *Pneumocystis*. Polychrome stains, such as Wright's, Giemsa, and methylene blue, will demonstrate nuclei of trophozoites and intracystic sporozoites in cytologic specimens, but the walls of cyst and trophozoites will not be apparent (see Fig. 68-5, A). The cysts of *P. carinii* do not reproduce by budding and should not be confused for small yeast-form fungi in GMS-stained tissue sections. Polarization microscopy has also been used to demonstrate *P. carinii* in tissues.¹

Gram	Unstained	Positive	Positive

Fig 68-9 *P. carinii* within alveolar spaces in a dog with *Pneumocystis* pneumonia. Only the nuclei of the organisms are visible making it difficult to identify. (Courtesy University of Georgia, Athens, Ga.)

Fig 68-10 *P. carinii* within alveolar spaces in a person with AIDS and *Pneumocystis* pneumonia. Light, honeycombed matrix contains trophozoites and cellular debris. Darker ovoid, irregular, and crescent-shaped structures are cysts (GMS, $\times 400$). See [Figure 68-1](#) for further orientation.

On histologic examination, alveolar spaces are filled with cohesive aggregates of amorphous, foamy, eosinophilic material that has a honeycomb-like pattern (see [Fig. 68-9](#)). A few macrophages and detached alveolar lining cells also may be present, but polymorphonuclear leukocytes are absent. Special staining methods are needed to identify cyst forms (see [Fig. 68-10](#)). Little or no phagocytosis of intact *Pneumocystis* organisms is present. However, nonviable organisms, such as those seen after treatment, are often phagocytosed, and macrophages may contain GMS-positive granular material that represents the residuum of cyst wall degradation. In some instances, alveolar septa are markedly thickened by dense accumulations of plasma cells, lymphocytes, and macrophages. The septa may be widened by fibrosis in chronic infections, especially after treatment. With GMS stain, cyst forms appear as spherical, ovoid, or crescent-shaped structures that range from 4 to 7 μm in diameter and have dotlike, argyrophilic, focal, cyst wall thickenings ([Fig. 68-11](#)). Cyst walls also can be demonstrated with other stains (see [Table 68-1](#)), and they will fluoresce when stained with orange G of a Papanicolaou stain. Trophozoites in tissue sections and smears are best demonstrated with Giemsa stain, especially Wolbach's procedure. On ultrastructural examination, intact alveoli are filled with compact aggregates of trophozoite and cyst forms. Trophozoites commonly line alveoli.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 68-11 Pulmonary pneumocystosis. Alveolar space contains thin-walled trophozoites (*T*) and a cyst form (*C*) of *P. carinii*. Segmental, lamellated thickening of cyst wall (*arrow*) corresponds to darkly stained “intracystic” foci seen by light microscopy (transmission electron microscopy uranyl acetate and lead citrate, $\times 22,000$). *Inset*, *P. carinii* cysts in touch imprint contain spherical to oval foci of enhanced staining (*arrows*) that in profile are contiguous with cyst wall (GMS, $\times 560$).

68.7 THERAPY

Supportive care is essential for any patient with pneumocystic pneumonia because of disturbed alveolar gaseous exchange. Oxygen therapy administered by cage, mask, or intubation is needed, and ventilatory assistance may also be required. Bronchodilators may help reduce airway resistance. If a patient is receiving immunosuppressive

Infectious Diseases of the Dog and Cat, 3rd Edition

agents, they should be temporarily discontinued; however, antiinflammatory drugs may be indicated. Antimicrobial chemotherapy of pulmonary pneumocystosis results in a decline in arterial oxygen related to the inflammatory reaction to dying organisms. Administration of antiinflammatory doses of glucocorticoids has been shown to improve pulmonary function and survival in people,^{2,9,40} although subsequent studies have not been as supportive.¹⁹ Immunosuppressive levels of glucocorticoids should *never* be given because they are known to facilitate the unchecked replication of the organism and fatal dissemination in people and experimental animals.

Specific chemotherapy is most beneficial in cases in which the disease is suspected or diagnosed during its early stages (Table 68-2). Despite their close genetic resemblance to fungi, *Pneumocystis* organisms are most sensitive to drugs used to treat protozoal infections. The two major chemotherapeutic agents that have successfully been used to treat pneumocystosis are pentamidine isethionate and the combination of trimethoprim and sulfonamide (TMS).

656

657

Table 68-2 Therapy for Pneumocystosis

DRUG ^a	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (WEEKS)
Specific Agents				
Trimethoprim-sulfonamide	15–20 mg/kg	PO	8	3–16 ^c
	30 mg/kg	PO	12	3
Pentamidine isethionate	4 mg/kg	IV, IM	24	3
Trimetrexate	45 mg/m ²	IV	24	3
Clindamycin and primaquine	3–13 mg/kg	PO	8	3
Atovaquone	15 mg/kg	PO	24	3
Adjunctive Agents				
Aminophylline	10–20 mg/kg	PO	8	3
Prednisone	1 mg/kg	PO	12–24	1
Cimetidine	5 mg/kg	PO	12	3
Levamisole	5 mg/kg	PO	48	3

PO, By mouth; IV, intravenous; IM, intramuscular.

- a See Drug Formulary, [Appendix 8](#), for additional information on each drug.
- b Dose per administration at specified interval.
- c Trimethoprim-sulfonamide is generally used alone or following remission with one of the other drugs. Treatment duration depends on the response to therapy. With use beyond 4 weeks, periodic monitoring for myelosuppression from folate synthesis antagonism is essential. Clinical response is monitored by repeated thoracic radiography.

Pentamidine isethionate is an aromatic diamidine that has been provided to reduce fatalities from the disease in people. Its major side effects include impaired renal function, hepatic dysfunction, hypoglycemia, hypotension, hypocalcemia, urticaria, and hematologic disorders (see [Chapter 71](#)). Serum urea nitrogen and glucose are monitored daily during treatment, and the drug is discontinued or dosage is reduced if complications or azotemia occur. Intramuscular (IM) and intravenous (IV) administration of pentamidine is associated with local inflammation and systemic hypotension, respectively, in people such that aerosolized delivery has been the preferred route of administration. IM administration of this drug has been successful in treating a dog with pneumocystosis with the only side effect being localized pain at the injection site. To lower its toxic side effects, pentamidine also has been successful, at a reduced dosage, in combination with sulfonamides. Levocovorin (folic acid) has been used as a supplement to avoid myelosuppression during long-term treatment.⁵⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

The combination of TMS has been found more effective and less toxic than pentamidine in treating and preventing *Pneumocystis* pneumonia in immunodeficient people. A relatively high oral dosage of 30 mg/kg given every 6 hours for 2 weeks has been recommended in people so that the drug reaches therapeutically effective serum concentrations. Long-term (up to 2 years) prophylactic therapy for pneumocystosis at this dosage has not caused bone marrow toxicity in children, although changes in oral and fecal microflora have been noted as has increased prevalence of mucocutaneous candidiasis.

In dogs, treatment has been reported in eight dogs,^{32,38,53} and four were dachshunds that recovered with treatment.³² A TMS dose of 15 mg/kg, every 8 hours, or 30 mg/kg, every 12 hours, for 3 weeks was used in treating these dogs; the longest reported followup in these studies was for 4 months. Only one King Charles spaniel has been successfully treated, and the followup has been for a 3-year period (Fig. 68-12,A and B).³ TMS was initially administered at a dose of 15 mg/kg, every 8 hours, daily for 4.3 months. After this time, medication was discontinued because of clinical resolution of signs of dyspnea, exercise intolerance, and pulmonary infiltrates, and the development of nonregenerative anemia suspected from folate antagonism. During the subsequent 3 years of monitoring, maintaining remission has required two re-treatment periods of 45 and 208 days in length. For dosage recommendations in treating dogs or cats, see Table 68-2.

In human infections, IV TMS therapy has been shown to be as or more effective than is oral therapy and has the advantage of ease of administration in severely depressed or comatose patients. Unfortunately, genotypic resistance to sulfonamides has been noted among some strains of *P. jiroveci* isolated from people.¹² Folic acid supplementation should be given if side effects such as leukopenia and anemia are observed or if long-term therapy is required.

Atovaquone, a hydroxynaphthoquinone, is licensed for the treatment of people with pneumocystosis.^{28,50} This drug is not as effective as is pentamidine or TMS but has lower toxicity. Bioavailability is increased when the drug is given with food with a high fat content. It also has been used, as has pentamidine, in aerosol administration.¹⁵

Combination therapy using clindamycin and primaquine has been effective in vivo and in vitro, but neither drug is effective alone. Further investigation on the naturally occurring disease is needed. Aromatic diamidines, such as diminazene, imidocarb, and amicarbalide, have been more effective than pentamidine in treating experimental *P. carinii* pneumonia (see Chapter 71). Dapsone and trimethoprim or pyrimethamine, in combination, has been effective in experimental animals and clinical trials in immunosuppressed people with pneumocystosis.²⁹ Trimetrexate, a lipid-soluble antifolate, has been given concomitantly with leucovorin in people with *Pneumocystis* pneumonia and AIDS. As with most of the other drugs, neutropenia with or without thrombocytopenia has been the main side effect. In experimentally infected animals, *P. carinii* is resistant to imidazole antifungal drugs,⁵ but the anthelmintics benzimidazole and albendazole have been effective.⁴ Dapsone, alone or in combination with trimethoprim or pyrimethamine, has potent anti-*Pneumocystis* activity in vitro and in animal studies.²⁹ When given at weekly, biweekly, or monthly intervals dapsone appeared effective in clearing organisms in the lung and might serve as a prophylactic measure to prevent infection in people.

657

658

Infectious Diseases of the Dog and Cat, 3rd Edition

Pneumocystosis in people and animals is *prima facie* evidence of immunodeficiency. For this reason, prophylactic treatment with TMS has been used in hospitalized people who are receiving irradiation or immunosuppressive agents or who have immunodeficiencies and debilitating diseases. Nonspecific immunostimulants such as cimetidine and levamisole (see Immunotherapy, [Chapter 2](#)) have been given adjunctively to treat affected miniature dachshunds.²¹ Similar precautions are not warranted in pets because pneumocystosis has not been recognized with similar frequency in such instances.

68.8 PUBLIC HEALTH CONSIDERATIONS

Pneumocystis organisms are ubiquitous in the environment. The primary health risk is immunodeficiency syndromes. People and animals are exposed to the same environmental sources of *Pneumocystis*. Molecular and epidemiologic evidence does suggest that spread occurs between people because of localized outbreaks. Clinically affected people and animals have the greatest concentrations of organisms in their airway secretions. Host immunocompetence is the most critical factor in determining whether illness develops. Therefore the most potential risk for a person acquiring infection from a pet would be if the animal was clinically ill from *Pneumocystis* pneumonia and the person in close contact was immunocompromised.

69 CHAPTER 69 Protothecosis

Craig E. Greene

Pauline M. Rakich

Kenneth S. Latimer

69.1 ETIOLOGY

Protothecosis is caused by *Prototheca*, a saprophytic achlorophyllous alga that is closely related to the green algae of the genus *Chlorella*. In culture or tissue, the cells are spherical to oval and range from 1.3 to 13.4 μm in diameter and 1.3 to 16.1 μm in length. The size varies with the stage of development, the species, and the medium used for culture. Organisms have a hyaline cell wall approximately 0.5 μm thick; a granular, basophilic cytoplasm; and a small, centrally located nucleus. In smaller, immature forms, a nucleus may not be evident. Reproduction is by endosporeulation, with irregular nuclear and cytoplasmic cleavage resulting in 2 to 20 or more endospores. The mother cell ruptures, discharging tiny replicas that enlarge, mature, and repeat the life cycle. Empty cell casings scattered among intact algal cells may be seen in lesions. [Figure 69-1](#) shows typical *Prototheca* in tissue.

Of the three recognized species of *Prototheca*—*Prototheca stagnora*, *Prototheca zopfii*, and *Prototheca wickerhamii*—the last two have been incriminated as pathogens. The species can be differentiated by sugar and alcohol assimilation tests or by fluorescent antibody (FA) methods.

69.2 EPIDEMIOLOGY AND PATHOGENESIS

The disease has been identified in people and animals in Europe, Asia, Africa, Australia, islands of the Pacific Ocean, and North America; a preponderance of the cases in North America are restricted to the southeastern United States.¹⁸ Ecologically, *Prototheca* species are primarily found in raw and treated sewage, slime flux of trees, and animal wastes.³¹ From these sources, *Prototheca* organisms secondarily contaminate water systems, soil, and food, from which they may be ingested by or come into contact with injured skin or mucosa of people and animals. Although *Prototheca* organisms can be isolated from freshly voided human and animal feces, the algae are regarded as transient contaminants and only rarely cause disease. Protothecosis is a sporadic illness that primarily develops when the host's immune resistance is suppressed or altered, often by a preexisting or concurrent disease. People with hematologic malignancies and who are receiving chemotherapy have been highly susceptible.⁴¹ Lack of cell-mediated immunity seems to be a more important factor than decreased humoral responses in allowing entrance of *Prototheca* organisms into tissues and establishment of infection. An association has been made between the development of protothecosis and the acquired immune deficiency syndrome (AIDS) in people.^{22,46} Infections have also occurred in people at sites of prolonged endotracheal intubation or peritoneal catheterization.^{14,19} Another pathogenetic mechanism noted in some infected people is a deficiency in the ability of the host's neutrophils to destroy *Prototheca* organisms after phagocytosis. No other evidence has been found of failure of either humoral immunity or cell-mediated immunity in such patients. Evaluation of immune function in one dog with disseminated protothecosis revealed depressed T-lymphocyte function and neutrophil inhibition.³² A serum inhibitory factor may have been responsible for both findings. Inflammatory infiltrates are minimal in active lesions with large numbers of organisms; however, mononuclear infiltrates increase once therapy is instituted and numbers of organisms decrease in the tissues.²⁹ In people with mild immunosuppression that

Infectious Diseases of the Dog and Cat, 3rd Edition

become colonized by *Prototheca* organisms, progression of the infection is accompanied by a reduction in measures of host immunosurveillance.³⁹

In people, infection is usually cutaneous, subcutaneous, or bursal, although mucosal, catheter-related, and disseminated infections also occur. Cutaneous and localized infections are frequently seen in cats. In contrast, in nearly all infected dogs, evidence of protracted colitis with multisystemic dissemination has been reported. This finding suggests that after ingestion by dogs, the colon may be the common site of replication, with the infection subsequently spreading to other organs by blood and lymph.

Virulence of the various *Prototheca* species may differ. Only *P. wickerhamii* has been isolated from dogs and cats with cutaneous infections. In contrast, *P. zopfii* is almost always isolated from dogs with disseminated infections. Breed susceptibility may also be a factor in dogs because a disproportionate number of cases have been reported in collies.⁴⁰ No age predilection is known, but a majority of the infected dogs are females.

69.3 CLINICAL FINDINGS

69.3.1 Dogs

The most frequently reported clinical observation in dogs is bloody diarrhea, which is usually intermittent and protracted. Melena or hematochezia may be observed. However, dogs generally develop widely disseminated disease; types and severity of clinical signs vary depending on the tissues involved. The kidney, liver, heart, intestine, brain, and eye are the most common sites of systemic dissemination. Weight loss and debility become more pronounced over the course of the disease. Clinical signs attributed directly to involvement of the central nervous system (CNS) have been reported in about 40% of the dogs and have included marked depression, ataxia, circling, incoordination, and paresis. Deafness has developed, as have signs of renal failure. Only a few cases of cutaneous infection have been reported in dogs. Skin lesions usually last for several months and are characterized by nodules, draining ulcers, and crusty exudates on the trunk, extremities, and mucosal surfaces (Fig. 69-2). Even in those with cutaneous infections, lesions may become disseminated, involving other organs such as the joints, lymph nodes, heart, and lungs.

The eyes are involved in two thirds of the cases, and in some dogs blindness may be the primary symptom. 659

Leukokoria resulting from vitreous clouding is common when dogs are first brought to the veterinarian for an examination.²⁴ Generally, ophthalmoscopic examination reveals exudative clouding of the fluid in one or both chambers and multiple white, raised foci or streaks in the retina (Fig. 69-3), often accompanied by small hemorrhages. Retinal detachment is usually evident. 660

Fig 69-1 *Prototheca* organisms in various stages of development; lesion in skin of dog with disseminated protothecosis. Dermis is replaced by numerous *P. zopfii* organisms, including young spherical cells (Y), more mature oval cells (M), sporulating cells (S), and scattered empty casings (C) of organisms (H and E stain, ×400). Infectious Diseases of the Dog and Cat, 3rd Edition

69.3.2 Cats

Only the cutaneous form of protothecosis has been reported in cats.^{8,11,12,20} Lesions usually consist of large, firm cutaneous nodules on the limbs or feet (Fig. 69-4). They have also been reported on the nose, forehead, pinna, and base of the tail. All cats were in good health otherwise. No published reports included results for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) status, making any association uncertain.

660

661

69.4 DIAGNOSIS

69.4.1 Clinical Laboratory Findings

Laboratory data have not been well characterized in cats and dogs with protothecosis. Generally, the results of the complete blood count (CBC) are within reference ranges. Rarely, serum hepatic enzyme activities are slightly elevated. Acute renal failure may develop in some dogs, resulting in azotemia and increase serum creatinine concentrations.^{31a} Abnormalities in the cerebrospinal fluid (CSF) may include marked pleocytosis (greater than 100 cells/ μ l), with granulocytes and lymphocytes being the predominant nucleated cell types, and an increased protein concentration (greater than 100 mg/dl).^{32,43}

69.4.2 Cytologic Examination

Whenever a dog that has ocular lesions and a history of protracted bloody diarrhea, protothecosis should be suspected. Diagnosis is often made by cytologic or histologic evaluation of affected tissues. For lower alimentary tract infections diagnosis can be made by cytologic examination of rectal and colonic scrapings (Fig. 69-5). Cytologic examination of scrapings is the most cost effective direct means of diagnosis. If necessary, full-thickness biopsy of the intestinal tract also can be performed. Fine-needle aspiration of other lesions also may be diagnostically useful. Cats that develop nodular and ulcerative skin lesions should also be checked for protothecosis. Because *Prototheca* organisms commonly invade Bowman's space and renal tubules after embolization, the presence of the organism in urinary sediment is an accurate indication that dissemination of infection has occurred (Fig. 69-6).^{31a,32}

69.4.3 Algal Identification and Isolation

For all lesions, microbiological isolation and identification is the most accurate way to confirm a diagnosis. Clinically, organisms have been found by culture of CSF or fluid obtained by vitreous centesis or fine-needle aspirates and from histologic evaluation of lesion biopsy specimens or enlarged lymph nodes.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 69-5 Protothecal cells (*arrows*) in smear of rectal scraping from dog with disseminated protothecosis. *P. zopfii* organisms vary in size and have granular basophilic to magenta cytoplasm surrounded by a clear capsule. Scattered columnar epithelial cells, erythrocytes, two neutrophils, and small lymphocyte are present also (Wright stain, $\times 1008$). (Courtesy Ken Latimer, University of Georgia, Athens, Ga.)

Prototheca species grow readily on various laboratory media, such as Sabouraud's cycloheximide-free dextrose agar at 25° C to 37° C, forming white to light tan colonies within 2 to 7 days. Characteristic organisms in all stages of development can be recognized by staining a smear from the colony with Gram iodine stain (Fig. 69-7). Ribostamycin-impregnated disks have been used to differentiate *Candida* and *Prototheca* colonies grossly on Sabouraud's glucose agar.⁵ *Prototheca* colonies develop a halo of inhibition around the disks, whereas *Candida* colonies do not. *Prototheca* species can be differentiated by the use of clotrimazole-impregnated discs, because *P. wickerhamii* is susceptible to clotrimazole, whereas *P. zopfii* is resistant.⁴ For specific differentiation, the slower but more routine method of culturing followed by sugar and alcohol assimilation testing can be done in most diagnostic laboratories.

Fig 69-6 Urine sediment from dog with disseminated protothecosis. *P. zopfii* organisms are numerous and exhibit anisocytosis and occasional sporulation. Scattered spermatozoa also are present (unstained urine sediment, $\times 1000$). (Courtesy Robert Duncan, University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

69.5 PATHOLOGIC FINDINGS

662

69.5.1 Dogs

Protothecosis is predominantly a disseminated disease, producing lesions in a wide variety of tissues. Lesions in parenchymatous organs and on serosal surfaces are diffusely scattered throughout the tissues as white to tan granular foci measuring 0.5 to 2 mm in diameter or as streaks measuring 0.5×2 to 3 mm wide. This pattern is particularly common in the myocardium, skeletal muscle, intestinal muscularis, lymph nodes, thyroid, liver, and loose connective tissue (Fig. 69-8).⁹ In the kidney, lesions tend to be larger, often measuring up to several centimeters, and are surrounded by a peripheral ring of hemorrhage. They also have a radiating linear pattern and may appear in either the cortex or medulla. Gross lesions may develop throughout the intestinal tract, but the colon is most commonly affected. The lesions in the mucosa may vary from diffuse reddening to marked nodular thickening and scattered, often hemorrhagic, ulcers. Tiny white foci are frequently seen in the muscularis and serosa. Sections of affected eyes contain gray-white cloudy exudates, often with red streaks, in one or both chambers and beneath the retina, which is often detached.

Fig 69-8 Heart and lungs of dog that died from disseminated infection with *P. zopffii*. Small, granular, white to tan foci are visible on surface of myocardium. (Courtesy Ken Latimer, University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 69-9 Sections of kidney **(A)** and heart **(B)** from dog with disseminated *P. zopfii* infection. **A**, Renal interstitium is infiltrated by *Prototheca* organisms. Inflammation is minimal and consists of a few lymphocytes and plasma cells (H and E stain, ×400). **B**, Myocardium contains large infiltrates of *Prototheca* organisms in absence of inflammation (H and E stain, ×400). (Courtesy Ken Latimer, University of Georgia, Athens, Ga.)

Microscopically, various host reactions may be seen. Inflammation is usually mild and composed of mixed inflammatory cells at the periphery of clusters of numerous *Prototheca* organisms (Figs. 69-9). The infiltrate consists of macrophages, lymphocytes, neutrophils, and plasma cells, which may be particularly numerous. Although less common, inflammation is pronounced and granulomatous or pyogranulomatous. In such lesions, macrophages and multinucleate giant cells contain many phagocytosed *Prototheca* cells. Hemorrhage and necrosis occur more commonly in the kidneys, heart, and intestines.

In the colon the mucosal surface is multifocally ulcerated and hemorrhagic. Masses of organisms, often arranged in cords or nodules, replace much of the mucosa and extend into and replace the submucosa. Small focal colonies of organisms are scattered throughout the muscularis and serosa. As in other tissues, inflammation is usually mild and composed of mixed cells. When infection is prolonged, granulation tissue may be intermingled with organisms in the mucosa and submucosa. In the kidney, multiple aggregates of *Prototheca* cells are distributed in the interstitium of the cortex, medulla, and occasionally the papillae. Inflammation and necrosis may vary from minimal to marked. Lesions in the brain and spinal cord usually develop as widely scattered, small foci of necrosis containing mixed inflammatory cells and rare to multiple aggregates of *Prototheca* cells. Similar lesions may be present in the inner ear. Focal to diffuse granulomatous chorioretinitis, retinal detachment, and severe retinal degeneration are the most common ocular lesions seen microscopically. Masses of organisms are in the vitreous and between the retina and choroid. Fewer develop focally in the choroid. The inflammatory infiltrate is mixed and may be pyogranulomatous.

In cutaneous lesions, masses of *Prototheca* cells are distributed in the dermis, subcutis, and subjacent skeletal muscle. The epidermis is variably hyperkeratotic, ulcerated, and inflamed. Ulcerated surfaces are commonly secondarily infected with bacteria. Cutaneous lesions may extend into the nasal mucosa and produce necrosis,

662

663

Infectious Diseases of the Dog and Cat, 3rd Edition

ulceration, hemorrhage, and infiltration of neutrophils and plasma cells mixed with large masses of proliferating *Prototheca*.³⁸ Typically the regional lymph nodes are invaded secondarily. In one dog with cutaneous protothecosis, inflammation before treatment was mild but increased during treatment even though the number of organisms decreased.²⁹ These findings suggested that viable organisms inhibited the immune response or were less immunoreactive in tissues than dead organisms.

P. zopfii and *P. wickerhamii* may have sufficient morphologic differences to be identified histologically⁷; however, the differences are too subtle for pathologists who see these organisms infrequently to make the distinction. When species identification is required, preserved biopsy and necropsy tissues and unstained histologic sections can be examined at specialized laboratories by the indirect FA technique.

69.5.2 Cats

Localized cutaneous lesions in cats consist of gray-white subcutaneous or dermal masses that extend deeply into the underlying tissue and infiltrate tendons, nerves, and blood vessels. Histologically, they are granulomas characterized by numerous epithelioid macrophages and scattered multinucleated giant cells. Neutrophils and plasma cells may be prominent in some lesions. Masses of *Prototheca* in all stages of reproduction constitute the bulk of the lesion.

69.5.3 Special Staining

Prototheca and *Chlorella* species are morphologically indistinguishable in tissues stained with hematoxylin-eosin (H and E) but can be differentiated using Gomori's methenamine silver (GMS) or periodic acid–Schiff (PAS) stain ([Fig. 69-10](#)). With these stains, large starch granules are seen in *Chlorella* species but not in *Prototheca* species. The presence of chloroplasts is characteristic of *Chlorella* species, but they are not visible in light microscopy of fixed tissues. No reports have been made of *Chlorella* organisms infecting dogs or cats; however, they have infected several other animal species and frequently are identified improperly as *Prototheca* species.

Infectious Diseases of the Dog and Cat, 3rd Edition

69.6 THERAPY

69.6.1 Cutaneous

Because protothecosis usually occurs as a single focal cutaneous lesion in people and cats, wide excision has been successful; and the preferred therapeutic approach for solitary lesions is resection in conjunction with systemic antimicrobial chemotherapy. Human cutaneous infections are usually caused by *P. wickerhamii*, which appears to be more susceptible to antifungal chemotherapy. In vitro studies on *P. wickerhamii* have shown a synergistic effect between amphotericin B (AMB) and other drugs such as tetracycline. Treatment of human cutaneous *P. wickerhamii* infection with AMB alone, in combination with oral tetracycline, or with ketoconazole (KTZ) or fluconazole (FCZ) has been successful.^{21,44}

One human with a *P. wickerhamii*-infected wrist wound was successfully treated with orally administered KTZ.²⁸ Hepatotoxicity, which developed in response to the treatment, resolved spontaneously after cessation of treatment. Chemotherapy with itraconazole (ITZ) resolved a dermal infection with *P. wickerhamii* in one person.²⁶ An immunocompetent person who developed a localized granuloma was also successfully treated with ITZ.³⁰ In a more unusual reported case of localized dermal *P. zopfii* infection, successful treatment

663

664

Infectious Diseases of the Dog and Cat, 3rd Edition

involved local infiltration of FCZ solution into the lesion.³⁶ In another case of localized *P. zopfii* infection in a person, amikacin and tetracyclines were combined for successful therapy.⁴⁷ Cutaneous *P. wickerhamii* infection in a human with AIDS did not respond to ITZ but did resolve with AMB therapy.² Susceptibility testing was predictive in this case and may be indicated in other cases of protothecosis because of the variable clinical responses achieved from various isolates from human and animal infections.

KTZ was effective in causing regression of multifocal cutaneous abscesses caused by infection with *Prototheca* species in a dog.²³ Treatment continued for 4 months, although long-term follow-up information was not available. The organism showed marked in vitro susceptibility to KTZ. In another dog with cutaneous manifestations of *P. wickerhamii* infection, oral KTZ therapy for 6 months resolved all the lesions except for a scrotal granuloma, which was surgically removed.¹⁵ However, a clinical relapse occurred 5 months later.

In vitro, clotrimazole (CTZ) is not effective for treating *P. zopfii* but is highly efficacious against *P. wickerhamii*.⁴ It is only available in topical preparations. Because cutaneous protothecosis in dogs and cats is caused by *P. wickerhamii*, topically applied CTZ might be the drug of choice for this form of protothecosis. Topical CTZ did not appear to alter the course of successful therapy with systemic KTZ in one dog.¹⁵

69.6.2 Disseminated

Various antimicrobial agents have been used to treat people and animals with disseminated infection. However, in most instances, treatment was unsuccessful. Therapies have included systemic administration of various antibacterial drugs, AMB, griseofulvin, potassium iodide, and pentamidine isethionate and topical application of antibiotics, copper sulfate, AMB lotion, gentian violet, brilliant green, and chlorinated lime.

A few human beings with disseminated protothecosis have been treated successfully with AMB and transfer factor.¹⁰ An immunocompetent person with disseminated *P. wickerhamii* infection was successfully treated with AMB for several weeks in conjunction with 3 months of KTZ treatment.⁶

Table 69-1 Proposed Systemic Drug Therapy for Protothecosis^a

DRUG ^b	SPECIES	DOSE (MG/KG) ^c	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)

IV, Intravenous; PO, orally.

- a For topical therapy a 3% amphotericin B solution for enemas and clotrimazole cream for cutaneous application are available.
- b See Drug Formulary, [Appendix 8](#), for additional information on each drug.
- c Dose per administration at specified interval.
- d Until cumulative dose is 8–12 mg/kg. Higher doses of lipid formulations are used; see Drug Formulary, [Appendix 8](#).
- e Until cumulative dose is 4 mg/kg. Higher doses of lipid formulations are used; see Drug Formulary, [Appendix 8](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

f Continue while receiving amphotericin B. More effective against *Prototheca wickerhamii* than *Prototheca zopfii*.

Dogs often develop the disseminated disease, and consequently the prognosis is guarded to poor. Unfortunately the disease is insidious, often widespread, and often involves many organs by the time clinical signs are evident. Ocular involvement causes endophthalmitis, which results in visual loss. Diarrhea may wax and wane initially, but it progresses inevitably. Treatment may prolong the course of infection, but the outcome is invariably fatal. Of almost 30 cases of disseminated *P. zopfii* infection reported in dogs since 1969, treatment has been uniformly unsuccessful in eliminating infection or preventing dissemination.

Aminoglycosides such as gentamicin have in vitro activity against *Prototheca*, but their clinical usefulness has not been well substantiated.^{17a} Ribostamycin, an aminoglycoside antibiotic closely related to kanamycin, is an effective agent in vitro against all species of *Prototheca*, especially *P. zopfii*.³ Although not commercially available, ribostamycin was used experimentally to treat a dog with chorioretinitis as the primary manifestation of infection with *P. zopfii*.³⁴ The drug was administered at a dose of 12.5 mg/kg given intramuscularly twice daily. Ocular manifestations improved, but the dog later died with disseminated lesions.

AMB was not effective in the treatment of ocular protothecosis (*P. zopfii*) in a dog.²⁵ The initial treatment reduced the size of the lesion in the eye, and blood culture results became negative, but therapy was discontinued because renal toxicity developed. Subsequently, lower doses failed to stop the progression of the lesions. Simazine (an algicidal drug used to clean fish tanks), gentamicin, and KTZ also were tried in the same dog without success. In another dog with ophthalmic lesions, ITZ therapy did not eliminate the lesions; however, the progression of infection was slowed, and the dog survived for 11 months.³⁵

In one dog with protothecal colitis, treatment with KTZ for 30 days may have slowed the progression of illness; the dog had a 4-month period of clinical remission after treatment.³³ In another dog with *Prototheca* enterocolitis, systemic AMB therapy was followed by an enema with 3% AMB cream.³⁷ Some of the clinical signs resolved, and the number of organisms in colonic cytologic specimens decreased. The dog was discharged from the hospital receiving a maintenance treatment of ITZ for 4 weeks; however, it died 6 weeks after treatment was instituted.

Treatment with AMB alone was successful in slowing the progression of clinical signs for 1 year in a dog with cutaneous and systemic infection with *P. wickerhamii*.⁴⁵ The more favorable outcome in this case may be because *P. wickerhamii* is more susceptible to antifungal drugs than *P. zopfii*. 664 665

Based on previous reports and in the absence of susceptibility data, disseminated disease in dogs caused by *P. zopfii* should be treated with AMB alone or in combination with ITZ. Aminoglycosides or tetracyclines could be alternative additional drugs. See Table 69-1 for appropriate drugs dosages for treating protothecosis.

69.7 PUBLIC HEALTH CONSIDERATIONS

Protothecosis is considered to be acquired from environmental exposure and is not transmissible between hosts. People, dogs, and cats are continually exposed to this ubiquitous organism but infrequently develop disease. Immunocompetent people and animals have less risk of developing clinical disease or dissemination than individuals with compromised immunity. Handling wastes or exudates from infected pets carries no greater risk of infection than environmental exposure. However, in general, immunocompromised people should be advised to

Infectious Diseases of the Dog and Cat, 3rd Edition

avoid close contact with infected animals. People who are hospitalized and receiving immunosuppressive or surgical therapy or those with intravenous, endotracheal, or peritoneal catheters are at greatest risk for infection.

70 CHAPTER 70 Laboratory Diagnosis of Protozoal Infections

Susan E. Little

Protozoa are responsible for some of the easiest and some of the most difficult infections to diagnose in clinical practice. When organisms are readily apparent and present in large numbers, diagnosis can be quickly achieved by direct microscopic examination of appropriate samples. However, in many cases, the protozoal organisms responsible for an infection are not present in high numbers, are not being shed or circulating at the time of sample collection, or they are difficult to identify because of their small size, subtle diagnostic features, or because of damage associated with mishandling of the sample before submission for diagnosis. Detection of organisms can also be hindered by prior treatment with antimicrobials. Although immunologic and molecular assays are becoming increasingly available to aid in the diagnosis of protozoal infections in dogs and cats, direct microscopic examination of feces, blood, or other clinical samples remains the mainstay of reaching a diagnosis for most of these organisms.

Many of the assays described in this chapter can be readily performed in clinic by trained personnel. However, because confirmation and consultation are often desired when reaching a diagnosis of an unusual parasite, collection and preservation of samples for submission to veterinary diagnostic laboratories are also discussed. Detailed descriptions of diagnosis of specific protozoal infections also are available in the appropriate chapters of this text.

70.1 MICROSCOPIC EXAMINATION

70.1.1 Feces

Protozoa are commonly found in fecal samples. Although samples should ideally be examined as quickly as possible following collection, some stages of some protozoans will still be evident in refrigerated or fixed samples.

70.1.1.1 Collection and Storage of Feces

To maximize the likelihood of identifying a parasite, at least 5 g of feces should be collected and placed in a clean, dry, airtight container. The amount of material retrieved by use of a fecal wand is insufficient for reaching a diagnosis of most intestinal parasites. Although interpretation of a positive result on direct smear from a fecal wand sample is possible, a negative result is all but meaningless because of the small sample size examined. If possible, the fecal sample should be held at room temperature and examined immediately (within 30 minutes) after collection. Protozoal trophozoites may lyse during refrigeration or long-term storage and thus fail to be detected. If samples cannot be examined immediately, however, then feces should be refrigerated. Tightly sealed, refrigerated samples may be examined for the presence of cysts or oocysts, which are hardier and persist in the environment for up to 1 week after collection.⁷

70.1.1.2 Examination of Feces

Table 70-1 lists the recommended microscopic procedures for the diagnosis of intestinal protozoal infections.

Infectious Diseases of the Dog and Cat, 3rd Edition

70.1.1.2.1

Direct Saline Smear

The direct smear technique, which can be performed on diarrheic or formed fecal samples, is most important when used with diarrheic specimens. To enhance detection, the substage condenser of the microscope should be adjusted to maximize contrast; unstained organisms may otherwise be overlooked. When available, the phase-contrast or dark-field microscope may aid in the demonstration of motile trophozoites but is not a necessary piece of equipment for reliable diagnosis of protozoal infection.

A direct smear is made by placing a drop of saline on a clean microscope slide and then mixing in a minute amount of fecal material; the amount that adheres to the tip of a wooden applicator stick is sufficient. A coverslip is then applied and the slide systematically scanned using the 10× objective but alternating with the 40× objective whenever structures morphologically resembling protozoal trophozoites or cysts are encountered. The fecal-saline mixture should be transparent enough that newsprint can be easily read through the material. Motility and structural features of protozoa are best examined using the high-dry objective (40× to 43×). The oil immersion objective (100×) is not recommended for examining fresh wet mounts because pressure on the coverslip from the oil objective displaces the fluid medium between the coverslip and the slide, making viewing difficult. If necessary, once motility has been observed, stain may be added to the smear to aid in specific identification of the organisms.⁹

70.1.1.2.2

Stained Smear

Although not required, adding stain to the wet mount through the edge of the coverslip may aid in visualizing internal structures of some protozoa. Because staining the preparation kills the organism, examination for motility must be performed first. [Table 70-2](#) describes the trophozoites found on direct smears from fecal samples of dogs and cats.

Iodine is the most common stain used to reveal the internal structure of protozoans and is especially useful for confirming the identity of *Giardia* cysts and trophozoites. The iodine stains the cytoplasm of cysts dark gold, while the nuclei remain pale and refractile. Other stains used to identify protozoa in feces include methylene blue, acid methyl green, aqueous eosin, and crystal violet. Methylene blue is useful for identifying trophozoites, especially those of *Entamoeba histolytica*, while acid methyl green stains the macronucleus of *Balantidium coli*. Aqueous eosin and crystal violet are both negative stains, which stain fecal debris but leave parasitic cysts and trophozoites, which exclude the dye, highlighted by their colorless appearance against the stained background.²

668

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 70-1 Recommended Procedures for the Diagnosis of Gastrointestinal Protozoans of the Dog and Cat

ORGANISM	STAGE	PROCEDURE
<i>Balantidium coli</i>	Trophozoites	Direct smear
	Cysts	Zinc sulfate centrifugation flotation technique
<i>Coccidia</i> (<i>Toxoplasma</i> , <i>Isospora</i> , <i>Sarcocystis</i> , <i>Hammondia</i> , <i>Besnoitia</i> , and <i>Cryptosporidium</i>)	Oocysts	Sheather's sugar centrifugation flotation technique
<i>Entamoeba histolytica</i>	Trophozoites	Direct smear
	Cysts	Direct smear
<i>Giardia</i>	Trophozoites	Direct smear, occasionally seen on flotation
	Cysts	Direct smear, zinc sulfate centrifugation flotation technique
<i>Pentatrichomonas</i>	Trophozoites	Direct smear

Table 70-2 Protozoal Trophozoite Identification by Direct Fecal Smear

ORGANISM	SIZE (µm)	DISTINGUISHING MORPHOLOGY	
		FRESH SMEAR	STAINED SMEAR
<i>Balantidium coli</i>	50–150	Oval shape; revolving movement by means of cilia; macronucleus may be visible	Large kidney bean—shaped macronucleus is prominent; occasionally micronucleus may be seen
<i>Entamoeba histolytica</i>	12–50	Constantly changes shape when active; moves by means of finger-like projections of cytoplasm; one nucleus that is difficult to see; may contain erythrocytes	Nucleus usually has evenly distributed peripheral chromatin and centrally located, compact karyosome
<i>Giardia</i>	9–21 × 5–15 × 2–4	Bilaterally symmetric; pear shaped on dorsoventral view; crescentic on lateral view; rolling movement by means of flagella; contains two nuclei	Two large nuclei, each with prominent karyosomes and axonemes and median bodies give monkey-faced appearance
<i>Pentatrichomonas</i>	5–20 × 3–14	Oval to pear shaped; wobbly, jerky, rapid movement by means of flagella; undulating membrane visible	Oval nucleus in anterior half of body; axostyle protruding from posterior end

70.1.1.2.3

Fecal Flotation

Fecal concentration methods are often necessary to reveal the presence of protozoal cysts or oocysts. With this technique, sugar or salt solutions are used with centrifugation to concentrate the cysts or oocysts present in several grams of feces into a small volume of fluid that can be examined on a single slide.

Infectious Diseases of the Dog and Cat, 3rd Edition

Standard sodium nitrate tabletop flotation alone is not adequate for detecting most protozoa, although coccidia oocysts are often revealed by this method. Although killed by the hypertonic solution and almost always lysed, trophozoites, especially those of *Giardia*, may also occasionally be seen on fecal flotation.

Solutions used in centrifugal fecal flotation methods include zinc sulfate and Sheather's sugar. Five to 10 g of feces are mixed with water to a liquid consistency, and the mixture is strained with gauze. Two parts Sheather's sugar solution (500 g sugar, 300 ml water, and 6.5 g melted phenol crystals) are added to one part fecal suspension and centrifuged in a capped centrifuge tube. Care should be taken not to fill the tube to the top to prevent spills or aerosols. After centrifugation at $1000\times G$ for 10 minutes, remove 1 to 2 drops from the meniscus by a dropper, place on a microscope slide, cover with a coverslip, and examine at low-power ($\times 100$) magnification. To assist in the examination of very mucoid or fatty fecal samples, 2 to 3 g of feces should first be combined with 5 to 10 ml of water, strained through a double layer of cheesecloth, the mixture centrifuged for 5 to 10 minutes at approximately $650\times G$, and the supernatant discarded. The sediment should then be mixed with 5 to 10 ml 33% zinc sulfate with a specific gravity of 1.18 or Sheather's sugar solution, strained through cheesecloth, and centrifuged for 5 to 10 minutes at approximately $650\times G$.⁹

668

669

When available, a centrifuge with a swinging bucket rotor is ideal for the flotation step. With this protocol, the strained feces–flotation solution mixture is poured into a 15-ml conical centrifuge tube and enough flotation solution added to form a reverse meniscus at the top of the tube. A coverslip is then placed on top of the meniscus and the tube spun with the coverslip in place; a second tube is needed to balance the centrifuge. Once completed, the coverslip is removed, transferred along with the adherent fluid to a slide, and the slide is examined. If only a fixed angle bucket rotor is available, fecal flotation with centrifugation can still be performed. In this case, the feces–flotation solution mixture should be poured into a 15-ml centrifuge tube to the point at which it is almost full but does not spill when placed into the centrifuge bucket (approximately 13 ml). The tube is then spun without a coverslip. After centrifugation is complete, the top layer of the centrifuged material can be collected by carefully touching the base of a small test tube or a microbiological loop to the surface and then transferring the adherent fluid to a slide. A coverslip is then applied and the preparation examined. Prepared slides should be completely examined using the $10\times$ and, when necessary to confirm the identification of an organism, the $40\times$ objectives. Scanning a slide at $4\times$ is not sufficient to allow detection of most protozoa.⁹

70.1.1.3

Preservation of Feces

If examining a fecal sample for protozoa is delayed, or if the sample is to be sent to a diagnostic laboratory for microscopic examination, the feces should be thoroughly mixed with a preservative before shipment. Enough fixative solution should be added to the feces to ensure adequate fixation. Some commonly used solutions include potassium dichromate, polyvinyl alcohol (PVA), and 10% formalin.²

Potassium dichromate is the solution of choice for storing samples containing oocysts of coccidia because it allows the oocysts to sporulate, permitting the precise measurements of sporocysts and sporozoites and complete evaluation of oocyst structure that are needed for identification. Historically, PVA has been considered the best choice for fixing trophozoites because permanently stained slides can be prepared from PVA-fixed fecal material. However, both PVA, which contains mercuric chloride, and potassium dichromate are potent toxicants and should be handled with great care. In recent years, less toxic, more environmentally safe substitutes for PVA have become available, including Proto-Fix (AlphaTec Systems, Inc., Vancouver, Wash.) and ECOFIX (Meridian Diagnostics, Inc., Cincinnati, Ohio).⁶

a May give negative results in seropositive animals.

70.1.2 Whole Blood

Protozoa may be detected in both fresh blood samples and in samples collected into anticoagulants. The most common method used to detect protozoa in blood is by preparing and staining a blood smear and examining the preparation microscopically. Blood-borne and systemic protozoa that can be detected in blood smears are listed in [Table 70-3](#).

70.1.2.1 Collection

Appropriate collection procedures for blood samples are dictated, in part, by the protozoa suspected to be the cause of disease. For samples from which blood smears will be performed, care should be taken in collection and handling the blood to avoid hemolysis that may destroy parasites and thus preclude detection. Smears from fresh whole blood should be made immediately following collection; samples of blood collected into ethylenediaminetetraacetic acid (EDTA) anticoagulant can be submitted for smears to be made at a later time. Some protozoa, especially *Babesia* spp., are more easily found in the peripheral circulation of microcapillary beds; detection of these parasites may be enhanced by collecting from an ear margin or clipped toenail.

70.1.2.2 Preparation of Blood Films

Preparing blood films that will be useful in diagnosis of parasitic protozoa requires care and skill. Thick films allow examination of a larger volume of blood, increasing the likelihood of detecting any parasitic protozoa present, but thin films are necessary to allow morphologic identification of the organisms. If possible, both thick and thin films should be prepared. When submitting slides to a diagnostic laboratory, multiple slides (at least two thick and two thin) should be prepared and submitted unstained.⁷

70.1.2.3 Thin Films

Thin films are prepared by placing a small drop of blood at one end of a clean microscope slide and then using a second slide to spread the blood. The short edge of the spreader slide is placed in the middle of the slide at a 30-degree angle and pulled back toward the blood. The blood is allowed to spread along the width

669

670

Infectious Diseases of the Dog and Cat, 3rd Edition

of the spreader slide; then, in a fairly rapid and even motion, the spreader slide is pushed across the length of the slide, dragging the blood along behind it. The blood should not be pushed across the slide because this will rupture many cells and parasites.

70.1.2.4 Thick Films

To prepare thick films, 2 to 3 drops of blood are placed on a clean microscope slide and spread with the corner of another slide in a circular motion over a 2-cm area. Fresh blood should be stirred on the slide for an additional 30 seconds to prevent formation of fibrin strands. EDTA-anticoagulated blood does not need to be stirred after spreading.⁷

Both thick and thin films should be air dried at room temperature on a flat surface. The choice of stain will determine the need for additional preparation and fixation before staining. Some stains require thick films to be laked (i.e., immersed in distilled water to rupture and remove erythrocytes) before staining. Thin films that are not stained within 48 hours should be fixed in 100% methanol. Both thick and thin films should be stored in a cool, dry, clean place in a sealed box.⁷

70.1.2.5 Staining Blood Films

Although personal preferences vary, Giemsa, Wright, and Wright-Giemsa are the most commonly used stains for detecting and identifying hemoproteoza on blood smears. Stains such as Diff-Quik can be used, but both detection of the presence of protozoa and subsequent morphologic identification to species are more difficult.⁵ Giemsa-stained blood smears have the added advantage of permanency; Wright-stained blood smears will fade over time.

70.1.2.6 Examination of Blood Films

Stained blood films may be examined with or without a coverslip. When a coverslip is not used, a drop of immersion oil can be placed on the stained smear to reduce diffraction and facilitate microscopic examination at low (10×) power and with the high-dry (43×) objectives. Additional oil should then be added and the feathered edge of the stained smear examined closely using the oil immersion (100×) objective. If preferred, a thin (#1) coverslip can be applied with neutral mounting medium before examination. The mounting medium prevents the coverslip from moving around on the stained smear and also reduces diffraction in a manner similar to immersion oil applied directly to the smear.⁷ One advantage of using a coverslip is that it allows the slide to be thoroughly cleaned with lens cleaner and reexamined at a later date by another diagnostician; the surface of stained smears that do not have a coverslip cannot be cleaned.

70.1.3 Other Samples

Protozoa may also be visualized directly by histologic examination of biopsy samples or tissues collected at necropsy or by direct microscopic examination of body fluids (other than blood), fine needle aspirates, and impression smears from biopsy samples. Blood-borne and systemic protozoa that can be detected in aspirates and impression smears are listed in [Table 70-3](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

70.1.3.1 Histopathology

Parasitic protozoa are often readily seen on histologic examination of tissues with routine hematoxylin and eosin staining. Special stains may be used to improve detection or enhance morphologic characteristics of the stage of parasite seen, allowing more confident identification. Tissue samples to be examined by histology should be collected and submitted quickly for frozen section when an immediate diagnosis is desired and resources to complete frozen section evaluation are available, or they should be placed in 10% formalin if processing will be delayed. Tissues on which electron microscopy will be performed should be placed in a glutaraldehyde-based fixative.⁷

70.1.3.2 Other Body Fluids

Protozoa are rarely found on direct microscopic examination of aqueous humor, cerebrospinal fluid, synovial fluid, urine, or transtracheal wash or bronchoalveolar lavage. *Giardia* trophozoites may occasionally be seen in duodenal aspirates collected at endoscopy. To determine if motile protozoa are present, all body fluids should be examined by direct smear immediately following collection; storage of samples for even a short period may result in lysis of organisms and subsequent failure to detect infection. Specimens are processed for examination by centrifuging collected fluid at $2000 \times G$ for 5 minutes and then making smears with the sediment and adding a small amount of associated fluid. After drying, smears should be stained as described for blood smears and examined for protozoa.

70.1.3.3 Fine Needle Aspirates

Protozoa are occasionally found in fine needle aspirates of lymph node, spleen, liver, and bone marrow. Aspirated material should be placed on a slide and then the material teased apart and thoroughly spread across the slide with a small-gauge needle to distribute it in a thin layer without disrupting cells. Alternatively, the material can be compressed between two slides and the slides pulled apart to distribute the material. Dried smears of fine needle aspirates are stained with Giemsa, Wright, or Wright-Giemsa and examined for protozoa as described for blood smears.

70.1.3.4 Impression Smears

Examination of stained impression smears of superficial lesions or of tissue collected at biopsy or necropsy may also reveal the presence of protozoa. For this reason, impression smears should be made of all biopsy material for which a protozoal diagnosis is suspected. Impression smears are made by blotting the cut edge of the tissue on an absorbent surface before touching the tissue to the surface of a glass slide. The small amount (ideally, a single cell layer) of material transferred to the glass slide is allowed to air dry and then stained and examined microscopically as described for blood smears.

70.2 CULTURE AND ANIMAL INOCULATION

70.2.1 Feces

Fecal protozoal culture is rarely performed in small animal practice. Specialized diagnostic laboratories that perform fecal culture must be identified before sample submission. See [Appendix 5](#) for a listing of these

Infectious Diseases of the Dog and Cat, 3rd Edition

laboratories. The sample should be fresh and sent by the most rapid means available; preservative should not be added to feces to be cultured. Although fecal culture for diagnosis of protozoal infections is rarely employed, specific media have been developed that will support the growth of *E. histolytica*, *B. coli*, and trichomonads. However, identifying enteric protozoa present in feces as specifically as possible is essential, based on morphologic appearance of the organisms before submitting samples for fecal culture.

Confirming the identity of some coccidia present in feces can be facilitated by inoculation of animals. This approach is most often reserved for pursuing research questions and is rarely undertaken in clinical veterinary medicine. The diagnostic laboratory or research facility that will perform the animal inoculation trials should be contacted before shipment of specimens for specific instructions on collection, handling, and transport of material. In general, feces containing oocysts suspected to be *Toxoplasma gondii*, *Neospora caninum*, or another coccidian of interest are shipped fresh to the research facility where the oocysts are collected from the feces and then fed to mice or another suitable intermediate host model. After allowing time for asexual stages to develop in the intermediate host, tissues are collected and examined to identify the species of parasite present.

670

671

70.2.2 Whole Blood

Although usually reserved for research projects, blood culture and animal inoculation with whole blood are occasionally performed to detect and document the presence of parasitic protozoa. However, because it is rarely performed for clinical diagnosis, protozoal blood culture or animal inoculation should be arranged with the laboratory before submission of samples and specific instructions obtained on sample collection and handling. In general, samples are collected aseptically into EDTA and then submitted to the participating laboratory as soon as possible.

70.2.3 Xenodiagnosis

Xenodiagnosis is another rarely performed procedure for clinical diagnosis in which laboratory-reared, parasite-free arthropods are allowed to feed on suspected infected hosts, and then, after appropriate time for development has elapsed, the arthropods are examined for the presence of parasites. Xenodiagnosis has historically been used for the diagnosis of trypanosomiasis but may also be useful in detecting other protozoal parasites.

70.2.4 Other Samples

In some cases, culture of tissue aspirates, biopsy samples, or body fluids other than blood may be desired. When indicated, an aliquot of the sample collected for cytologic evaluation is placed in a sterile tube at the time of collection. Culture or animal inoculation can then be performed with this sample as indicated. Rapid submission to an appropriate diagnostic laboratory will increase the likelihood of successfully culturing any protozoa present. To facilitate the process and receive exact instructions on sample handling and submission, the diagnostic laboratory to be used should be contacted before collection of samples. See [Appendix 5](#) for laboratories performing these tests.

70.3 ANTIGEN DETECTION

Protozoal antigen present in clinical samples may be detected by enzyme-linked immunosorbent assay (ELISA) or by staining via direct fluorescent antibody (FA) or immunohistochemistry. In these assays, specific antibodies bind to surface proteins of the protozoa of interest, and the bound antibody is detected through subsequent steps.

Infectious Diseases of the Dog and Cat, 3rd Edition

Although not a substitute for direct microscopic examination, these assays can augment diagnosis greatly by enhancing the detection of protozoa that are present in low numbers in clinical samples.

Commercial immunodiagnostic assays are available for detecting and identifying cysts of *Giardia* and *E. histolytica* and oocysts of *Cryptosporidium* spp. in feces. See [Appendix 6](#) for information on these test kits. Some of these assays, which were originally developed for use in diagnosis of human infections, have been successfully used in veterinary species, including dogs and cats. Comparison of zinc sulfate centrifugation flotation with an ELISA developed for use in human samples found that the flotation method was slightly more sensitive.³ Because false-negative results can occur, these tests should always be performed along with microscopic examination of feces following centrifugal concentration using an appropriate flotation solution.

Fine needle aspirates and biopsy samples can also be evaluated for the presence of parasite antigen. Aliquots of samples should be placed in a separate sterile tube at the time of collection and submitted to appropriate laboratories for direct FA or immunohistochemistry specific for the parasite in question. Paired samples should always be submitted for cytologic or histologic examination whenever direct FA or immunohistochemical detection is pursued.

70.4 NUCLEIC ACID DETECTION

Detection of nucleic acid sequences characteristic of a given protozoa also provides direct evidence of current or very recent infection. The most commonly used techniques for detecting protozoa in clinical research projects are polymerase chain reaction (PCR) and in situ hybridization. PCR amplification of specific gene sequences has been used extensively in research projects to evaluate fecal samples for the presence of *Giardia* spp. and *Cryptosporidium* spp. Although promising, this technique is not yet available for routine testing of clinical samples. PCR is also becoming increasingly important in evaluating blood samples for the presence of hemoprotozoa. Whole blood samples to be submitted for PCR assay should be collected into new blood tubes containing the anticoagulant specified by the testing laboratory; EDTA is the most common anticoagulant used in samples to be tested by PCR. PCR can also be performed on samples of other body fluids, fine needle aspirates, and biopsy samples. If they will not be assayed immediately, samples on which PCR will be performed should be frozen at the time of collection and held frozen until submission to the diagnostic laboratory. In situ hybridization involves detection of nucleic acid in tissue sections using labeled specific probes. At present, in situ hybridization is only performed at specialized research laboratories for a few protozoal parasites. Refer to [Appendix 5](#) for a listing of laboratories performing nucleic acid tests.

70.5 SEROLOGY

Serologic assays to detect antibodies reactive to parasitic protozoa of dogs and cats are widely available and provide indirect evidence of past or current infection. Although indirect FA tests are the most common type of serologic assay employed, ELISA and parasite agglutination tests are also available and are occasionally used to detect antibodies reactive to a given protozoa (see [Appendix 5](#)). Serology is not available for all parasitic protozoa of dogs and cats, and not all veterinary diagnostic laboratories are equipped to run the assays that are available. Individual laboratories should be consulted before submitting samples. Blood collected for serologic testing should be placed in a tube free of anticoagulant; care should be taken to prevent hemolysis during sample collection or handling. Serum separated from the clot may be frozen before testing. Details on the tests available and information on interpreting results can be found in the individual chapters for each protozoan.

Serologic testing for protozoal infections has several advantages, including ease of sample collection, low cost of most procedures, and wide availability of assays. However, most of these assays are based on detection of IgG,

Infectious Diseases of the Dog and Cat, 3rd Edition

which develops later in infection, often after clinical disease has begun, and remains elevated for months to years after initial infection, complicating interpretation of a single titer in a clinically ill animal. Diagnosis of active infection with an IgG-based test requires demonstrating a fourfold change in titer in two paired serum samples. In general, IgM is produced early in the course of an infection, and some IgM-based tests are available. However, the presence of antibodies in the serum does not correlate directly with clinical illness in all animals. Many healthy animals have detectable antibodies to protozoan parasites, and immunosuppressed animals may not develop antibodies despite infection and clinical disease. Different assays also vary in sensitivity and specificity. The diagnostic laboratory performing the assay should be consulted for assistance in interpreting results (see [Appendix 5](#)).

71 CHAPTER 71 Antiprotozoal Chemotherapy

Craig E. Greene

Sidney A. Ewing

Table 71-1 summarizes the indications for current antiprotozoal drugs. See Chapters 72 to 82 for details about chemotherapy for specific diseases. Dosages of various drugs are available in the Drug Formulary, Appendix 8.

71.1 AZO-NAPHTHALENE DRUGS

Trypan blue was one of the first compounds used to treat babesiosis. Because local irritation and abscesses develop after subcutaneous (SC) injection, it is administered intravenously (IV). Trypan blue does not completely eliminate *Babesia* organisms, but infected animals recover from illness and remain in a state of premunition. They must be treated with aromatic diamidines (see Aromatic Diamidines) within 1 month to be cured. A disadvantage of trypan blue is that it stains all body tissues and secretions for several weeks.

71.2 ACRIDINE DYES

Quinacrine, developed as a human antimalarial drug, has been administered to dogs as an alternative treatment to nitroimidazoles for giardiasis. It becomes incorporated into the DNA of the organism and inhibits nucleic acid synthesis. Evidence of toxicity includes vomiting, fever, pruritus, neurologic signs, yellow discoloration of urine and tissues, and hepatic dysfunction. It is no longer available in the United States.

71.3 QUINOLINE AND QUINOLONE DERIVATIVES

Diiodohydroxyquin and iodochlorhydroxyquin are halogenated oxyquinolines that have been provided as topical antifungal drugs. They are also amebicidal when administered orally. They are not absorbed systemically and have relatively low toxicity. Signs of toxicity are abdominal pain, diarrhea, and neurologic signs, all of which have been reported in dogs. Atovaquone is a closely related hydroxynaphthoquinone derivative licensed to treat *Pneumocystis* species infections. It has been used in combination with azithromycin to treat babesiosis in people and dogs (see Chapter 77).⁴⁴ Buparvaquone, which has been used to treat theileriosis in herbivores, has not effectively treated leishmaniasis or cytauxzoonosis in dogs or cats, respectively.⁹⁶ Decoquinatone, an hydroxyquinolone licensed for treating coccidiosis in poultry, is effective in ameliorating the signs of hepatozoonosis (see Chapter 74 and Drug Formulary, Appendix 8).⁵⁴

71.4 AROMATIC DIAMIDINES

Phenamidine, pentamidine, diminazene, amicarbalide, and imidocarb, which are diamidine derivatives, are the drugs of choice for treating *Babesia*, *Cytauxzoon*, and African *Trypanosoma* species infections in dogs and cats. They also effectively treat some other protozoa (see Table 71-1) by interfering with nucleic acid metabolism. These drugs are formulated as salts to reduce irritation after parenteral (intramuscular or SC) injection. Pentamidine has also been used to treat leishmaniasis.⁷⁷

Diamidines are rapidly effective and usually resolve clinical signs and parasitemia within 24 hours. They do not completely eradicate the organisms but have residual activity after a single injection. The drugs become highly

Infectious Diseases of the Dog and Cat, 3rd Edition

concentrated in parenchymal organs such as the liver and brain and are slowly metabolized or excreted unchanged. The slow metabolism and elimination of diamidines contribute to their prophylactic effects for many weeks after a single injection. Subtherapeutic dosages may allow organisms to develop resistance to these drugs.

71.5 NITROIMIDAZOLES

Nitroimidazoles are effective against anaerobic enteric protozoa that cause trichomoniasis, amebiasis, giardiasis, and balantidiasis. They can be used to treat intrainestinal and invasive parasites. The nitrogroup within anaerobic protozoa and bacteria undergoes a reduction to produce various unstable metabolites, some of which have antimicrobial activity. The drugs are generally much less effective against microaerophilic or aerobic microorganisms. Metronidazole, tinidazole, nimorazole, dimetridazole, secnidazole, and ornidazole are close structural analogs marketed in various regions of the world. Metronidazole is the most widely used of these compounds. In addition to protozoa, it is active against obligate spore-forming anaerobes such as *Clostridium*, some non-spore-forming anaerobes such as *Campylobacter*, and microaerophilic organisms such as species belonging to the Enterobacteriaceae. Metronidazole is generally preferred for treating giardiasis.⁸³ *Giardia* infections that are resistant to metronidazole have been effectively treated by combining treatment with quinacrine.⁶⁶ Metronidazole is the drug of choice for treating invasive amebiasis in people.

674

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 71-1 Properties of Antiprotozoal Drugs

GENERIC NAME (TRADE NAME) ^a	INFECTIONS INDICATED	
	FIRST CHOICE	ALTERNATE CHOICE
Azo-Naphthalene Dyes		
Trypan blue	None	<i>Babesia</i>
Acridine Dyes		
Quinacrine hydrochloride (Atabrine, Keybrin)	None	<i>Giardia</i>
Quinoline and Quinolone Derivatives		
Diiodohydroxyquin (iodoquinol; Diodoquin, Yodoxin)	<i>Balantidium</i>	<i>Entamoeba</i>
Iodochlorhydroxyquin (clioquinol; Vioform)	<i>Balantidium</i>	<i>Entamoeba</i>
Decoquinat (Deccox)	<i>Hepatozoon</i>	Coccidiosis
Hydroxynaphthoquinones		
Atovaquone (Mepron)	None	<i>Babesia</i> , <i>Pneumocystis</i> , <i>Toxoplasma</i>
Aromatic Diamidines		
Pentamidine isethionate (Lomidine, Pentam, NebuPent); also phenamidine	<i>Babesia</i> , <i>Acanthamoeba</i>	<i>Leishmania</i> , <i>Pneumocystis</i>
Diminazene aceturate (Berenil, Ganaseg)	<i>Cytauxzoon</i> , <i>Babesia</i> , African <i>Trypanosoma</i>	<i>Hepatozoon canis</i>
Imidocarb dipropionate (Imizol)	<i>Babesia</i> , <i>Hepatozoon canis</i> , <i>Cytauxzoon</i>	<i>Ehrlichia</i>
Amicarbalide (Diampiron)	<i>Ehrlichia</i>	None
Nitroimidazoles		
Metronidazole (Flagyl, Stomorgyl ^b)	<i>Giardia</i> , <i>Pentatrichomonas</i>	<i>Entamoeba</i> (invasive), <i>Balantidium</i>
Dimetridazole (Emtryl)	<i>Entamoeba</i> , <i>Balantidium</i>	None
Tinidazole (Fasigyn)	<i>Pentatrichomonas</i>	<i>Babesia</i> , <i>Giardia</i>
Benzimidazoles		
Fenbendazole (Panacur)	Helminths, <i>Giardia</i>	None
Albendazole (Valbazan)	<i>Giardia</i> , <i>Encephalitozoon</i>	None
Febantel-Praziquantel-Pyrantel pamoate (Drontal-plus)	Helminths	<i>Giardia</i>
Ionophores		
Monensin (Rumensin, Coban)	Coccidia	<i>Toxoplasma</i>
Lasalocid (Bovatec)	Coccidia	None
Salinomycin (Bio-cox)	Coccidia	None
Antimonial		
Sodium stibogluconate (Pentostam)	<i>Leishmania</i>	None
Meglumine antimoniate (Glucantime)	<i>Leishmania</i>	None
Antibacterials		
Paromomycin (Humatin, Aminosidine)	<i>Cryptosporidium</i> , <i>Pentatrichomonas</i>	<i>Entamoeba</i> , <i>Giardia</i> , <i>Leishmania</i>
Furazolidone (Furoxone)	Coccidia	<i>Giardia</i>
Nifurtimox (Lampit)	<i>Trypanosoma cruzi</i>	<i>Leishmania</i>
Tetracycline, doxycycline (many formulations)	<i>Balantidium</i>	<i>Hepatozoon canis</i>
Trimethoprim-sulfonamide (Tribrissen, Ditrin, Bactrim, Septra)	<i>Pneumocystis</i> , Coccidia, <i>Cyclospora</i> , <i>Neospora</i>	<i>Acanthamoeba</i>
Pyrimethamine (Daraprim)	<i>Toxoplasma</i> , <i>Neospora</i>	<i>Pneumocystis</i>
Spiramycin (Rovamycin, Stomorgyl ^b)	<i>Cryptosporidium</i>	<i>Toxoplasma</i>
Clindamycin (Antirobe, Cleocin)	<i>Toxoplasma</i> , <i>Neospora</i>	<i>Babesia</i>
Azithromycin (Zithromax)	<i>Toxoplasma</i>	<i>Babesia</i> , <i>Cryptosporidium</i>

Infectious Diseases of the Dog and Cat, 3rd Edition

Miscellaneous		
Bismuth- <i>N</i> -glycolylarsanilate (Milibis-V)	None	<i>Entamoeba</i> , <i>Giardia</i>
Amprolium (Amprol, Corid)	None	Coccidia
Amphotericin B (Fungizone, Albect ^c)	<i>Acanthamoeba</i>	<i>Leishmania</i>
Phosphocholine (Oleyl-Pc, Miltefosine)	<i>Leishmania</i>	<i>Trypanosoma</i>
Toltrazuril (Baycox)	Coccidia	<i>Toxoplasma</i> , <i>Hepatozoon</i>
Ponazuril (Marquis)	<i>Neospora</i>	<i>Sarcocystis</i>
Ketoconazole (Nizoral)	<i>Leishmania</i>	None
Allopurinol (Zyloprim ^d)	<i>Leishmania</i>	<i>Trypanosoma cruzi</i>
Fumagillin	<i>Encephalitozoon</i>	<i>Entamoeba</i>
Suramin (Metaret)	African <i>Trypanosoma</i>	Feline leukemia virus
Interferon- γ ^d	<i>Leishmania</i>	None

a See Drug Formulary, [Appendix 8](#), for additional information on these drugs.

b Combination of metronidazole (25, 125, 250 mg) with spiramycin (46.9, 234, 469 mg) in tablets.

c Lipid formulations preferred.

d Used in combination with antimonials for leishmaniasis.

Metronidazole is almost completely absorbed after oral administration. Food does not reduce the extent of absorption but may delay the rate. IV administration of metronidazole may be preferable in severely ill patients but is expensive and potentially more neurotoxic. The drug distributes widely and penetrates body tissues, extracellular fluids, and even pus-filled cavities. Metronidazole achieves good concentrations in the central nervous system (CNS) even in the absence of inflammation. It is extensively metabolized in the liver, but renal excretion of active drug also occurs.

Metronidazole has been administered alone and with spiramycin to treat periodontal disease and stomatitis and in combination with aminoglycosides to treat mixed infections associated with bowel perforation and intraabdominal sepsis (see [Chapter 89](#)). In people the drug effectively treats intraabdominal, pelvic, pleuropulmonary, CNS, and bone and joint infections.

Side effects of metronidazole include gastrointestinal irritation with signs of vomiting and anorexia, glossitis, and stomatitis. Neurologic signs may be seen in dogs and cats after 7 to 10 days of treatment with high dosages (greater than 66 mg/kg/day) and may be resolved when therapy is discontinued.¹² Some dogs have developed fatal encephalopathy, persistent seizures, or cerebellar and central vestibular ataxia after therapy; diazepam helped the dogs recover (see Drug Formulary, [Appendix 8](#)).²⁰

71.6 BENZIMIDAZOLES

Fenbendazole and albendazole are broad-spectrum benzimidazoles that are used to treat a wide range of infections with helminths and selected protozoa. They affect microtubule synthesis in the protozoal cytoskeleton. Both drugs have been effective in the treatment of intestinal giardiasis and are often more potent than metronidazole.³⁰ Fenbendazole is relatively safe, and dosages used for treating helminths (50 mg/kg for 3 days) are effective in treating giardiasis.^{30,82,100} The drug was not as effective in cats that were coinfecting with *Cryptosporidium*.⁴¹ Fenbendazole use was associated with development of granulocytopenia as an idiosyncratic reaction in one dog.^{23a} Myelotoxicity has been caused by albendazole use in dogs and cats⁸⁹ but can be reversed after treatment is discontinued. Febantel, which is metabolized to fenbendazole, is one component of an antihelminthic combination that is effective against *Giardia*.^{6,70}

Infectious Diseases of the Dog and Cat, 3rd Edition

71.7 AZOLES

The antifungal drugs ketoconazole, fluconazole, and terbinafine have some antileishmanial activity, because the infecting organism has ergosterol in its cell wall. In experimental animal models, these drugs have been less effective than other antiprotozoal drugs. Another antifungal, amphotericin B (AMB), has been more effective (see below, Miscellaneous drugs).

674

71.8 IONOPHORES

Ionophores are compounds that form lipid-soluble complexes with cations, which facilitate transport of the ions across biologic membranes. They are antibiotics isolated from *Streptomyces* spp. and are provided primarily as coccidiostats. Monensin, lasalocid, and salinomycin, the compounds used in veterinary medicine, cause accumulation of intracellular ions within the parasite, interfering with its metabolism. They have been used primarily as growth promoters in food animal practice, although monensin has been effective in reducing shedding of *Toxoplasma* oocysts by cats. The ionophores also have antibacterial activity and have been used experimentally to treat endotoxic shock in dogs. Because of their stimulatory effects on cardiac contractility and myocardial perfusion, their toxicity may be increased by concurrent administration of cardiac glycosides.

675

71.9 ANTIMONIALS

Sodium stibogluconate and meglumine antimoniate are pentavalent antimony compounds and two of the main agents used in the treatment of leishmaniasis.^{27,84,91-93} The dosage is based on the amount of antimony compound administered. Treatment with these drugs is not curative, and two or three courses may be necessary. Side effects include anorexia, vomiting, nausea, myalgia, and lethargy. Electrocardiogram abnormalities and nephrotoxicity can develop at higher dosages. Although these antimonials are often given parenterally, a cyclodextrin formulation was found to have good bioavailability in mice.¹⁶

71.10 ANTIBACTERIALS

Paromomycin (aminosidine) and furazolidone are nonabsorbable antibacterials (previously discussed; see [Chapter 34](#)). They are effective in treating some intestinal protozoal infections. Because of potential intestinal absorption and nephrotoxicity, paromomycin—an aminoglycoside—must be administered with caution when treating amebiasis or trichomoniasis when bowel lesions are extensive. Paromomycin has also been used to treat leishmaniasis. Furazolidone and sulfonamides are effective in treating intestinal coccidial infections. Nifurtimox, a nitrofur derivative, can suppress but not cure *Trypanosoma cruzi* infections. Nausea, vomiting, and convulsions may be side effects.

Trimethoprim, an antibacterial diaminopyrimidine compound that inhibits folic acid synthesis, has broad-spectrum antimicrobial activity (see [Chapter 34](#)). Combined with sulfonamides, it has been used to treat *Pneumocystis* and coccidial infections. Pyrimethamine is closely related to trimethoprim but is more effective against protozoa. It has been used in combination with sulfonamides to treat infections with *Neospora* and *Toxoplasma* organisms.

Several newer antifolate drugs (see [Chapter 80](#)) under development may also be active against these two protozoa. Clindamycin, a lincosamide antimicrobial drug, and certain macrolides (azithromycin, clarithromycin) are also active against these two protozoa.

Infectious Diseases of the Dog and Cat, 3rd Edition

Spiramycin, a macrolide antibiotic, has an antibacterial spectrum similar to that of erythromycin but is less effective. Absorption after oral administration is adequate for therapeutic purposes. It is widely distributed and reaches high concentrations in tissues, from which it is slowly eliminated in the bile and urine. Its usefulness has been limited for treating bacterial infections in veterinary medicine, but it is now marketed in combination with metronidazole, primarily to treat periodontal and oral infections. Spiramycin has been found to be somewhat effective for treating intestinal cryptosporidiosis and has been given to people to treat acute toxoplasmosis.

71.1 MISCELLANEOUS DRUGS

Bismuth-*N*-glycolylarsanilate is an antihelminthic drug that is a second choice for treating giardiasis. Amprolium is a thiamine inhibitor that is commonly chosen to treat coccidiosis in dogs, although it is not approved by the Food and Drug Administration for this purpose (see [Chapter 81](#)). Overdoses may produce neurologic signs. As mentioned previously, the antifungal drug AMB is effective in treating leishmaniasis because the infecting protozoa have ergosterol in their cell walls. It is much more efficient than other drugs in treating human patients.⁶¹ Lipid emulsions may improve this efficacy and lower toxicity.¹⁵ Toltrazuril is an anticoccidial agent that is unrelated to the others. It appears to be very effective in eliminating coccidia in most animals without interfering with a persistent host immune response.^{25,26} Toltrazuril has been used to control oocyst shedding by cats acutely infected with *Toxoplasma* organisms.⁵² The drug can be given by mouth in water or food, systemically by SC injection, or by topical application. A sulfone derivative of the drug (ponazuril) is effective in treating *Sarcocystis neurona* infection in horses,²² and it has been used to treat *Neospora caninum* infection in calves and dogs⁴⁵ (see Drug Formulary, [Appendix 8](#)). Nitazoxanide is a thiazolide compound that has been approved for use in people with drug-resistant *Giardia* and *Cryptosporidium* infections. Allopurinol is a pyrazolopyrimidine that interferes with nucleic acid synthesis in *Leishmania* and *T. cruzi* organisms. It has been licensed to treat hyperuricemia and gout in people but is now being used to treat American trypanosomiasis and leishmaniasis in endemic areas (see [Chapters 72 and 73](#)). * Miltefosine (hexadecylphosphocholine) is a membrane active drug that accumulates in macrophages and is active against *Leishmania* while simultaneously stimulating T-cell activation and production of toxic intracellular intermediates. Although the orally administered drug has been effective in treating *Leishmania*-infected people,^{75,90} side effects are more severe in dogs, so other derivatives of phosphocholine are recommended (see Drug Formulary, [Appendix 8](#)). Anthelmintics containing febantel have been used to treat dogs with giardiasis.⁷⁰

72 CHAPTER 72 Trypanosomiasis

72.1 AMERICAN TRYPANOSOMIASIS

Stephen C. Barr

72.1.1 Etiology and Life Cycle

Trypanosoma cruzi, the etiologic agent of American trypanosomiasis or Chagas' disease, is a hemoflagellate protozoan of the class Zoomastigophorea and family Trypanosomatidae. The organism exists in three morphologic forms. The trypomastigote or blood form is 15 to 20 μm long, with a flattened spindle-shaped body and a centrally placed vesicular nucleus. A single, free flagellum originates from a basal body near the large subterminal kinetoplast (situated posterior to the nucleus) and passes along the body to project anteriorly (Fig. 72-1). The intracellular or amastigote form is approximately 1.5 to 4.0 μm in diameter and ovoid, and it contains a large, round nucleus and rodlike kinetoplast. The flagellum is small and not always obvious under light microscopy. Epimastigotes, the third morphologic form, are found in the reduviid vector (subfamily Triatomae), commonly known as the kissing bug. This flagellated and spindle-shaped form has a kinetoplast situated anterior to the nucleus.

Infection usually occurs when trypomastigotes are deposited in the insect vector's feces at the bite site (Fig. 72-2). Oral ingestion of infected insects will cause infection in opossums and might be a possible route of infection in dogs.⁷⁹ Other less common sources of infection include blood transfusions, congenital factors, or ingestion of meat or milk from infected lactating animals.²⁴ Trypomastigotes usually enter macrophages and myocytes, either locally or systemically, after hematogenous spread. Once they are intracellular, trypomastigotes transform into amastigotes, which multiply by binary fission. These amastigotes transform into trypomastigotes before rupture of and release from the cell. Rapid intracellular multiplication cycles ensure a rapid rise in parasitemia before effective immunity develops. The vector becomes infected by ingesting circulating trypomastigotes, which transform to epimastigotes and multiply by binary fission. Transformation of the epimastigotes back into trypomastigotes occurs in the vector's hindgut before the trypomastigotes are passed in the feces (Fig. 72-2).

Trypanosoma evansi, or a closely related trypanosome, has been isolated from animals in the Pantanal region of Brazil.^{6,95} *T. evansi* has previously been isolated from animals in the Eastern hemisphere.

72.1.2 Epidemiology

72.1.2.1 *T. cruzi* Infection

T. cruzi infects people and a wide range of domestic and wild animal species in the Americas (Fig. 72-3, A). It is a major human health problem in South America (especially Brazil, Venezuela, Argentina) and Central America and is gaining importance in Mexico. Few human cases involving transmission by vectors have been reported in the United States. However, a large number of people have emigrated from endemic regions to the United States, where an estimated 50,000 to 100,000 *T. cruzi*-infected people now reside.

Consequently, the number of cases associated with blood transfusion transmission have steadily risen.^{61,104}

Screening of canine blood donors for this infection has also been controversial.¹¹⁸ Most canine cases in the

Infectious Diseases of the Dog and Cat, 3rd Edition

United States, the number of which in fact may be rising, occur in Texas, especially in areas close to the Mexican border.^{10,78} Isolated canine cases occur in other southern states,^{*} although the infection was found to be endemic in a group of Walker hounds in Virginia.²⁴ A bitch and a majority of her pups were found to be infected, suggesting transplacental or transmammary infection. Other kennels of dogs have been studied throughout the United States for evidence of serum antibody titers to *T. cruzi* (see Fig. 72-3, B). Presumably, vector and other means of transmission maintain infection within these populations. Transplacental transmission has been experimentally documented in rodents suffering acute parasitemia following inoculation before conception with a dog strain of *T. cruzi*.⁸⁰

677

Fig 72-1 Trypomastigote form of *T. cruzi* in a blood film (Wright, ×1000).

Usual transmission of *T. cruzi* in endemic countries depends on the confluence of reservoirs, vectors, parasites, and hosts (people or animals) in a single habitat. Two extremes of vector behavior have been noted: those that are habitually domiciliated and those that are habitually sylvan; many species are intermediate in behavior. Because of this variation, vectors tend to have either domestic or sylvan cycles, with crossover between the two occasionally. Of the many triatomid species that can feed on people in South America, only three, *Triatoma* spp., *Triatoma dimidiata*, and *Rhodnius prolixus*, are related to the epidemiology of human infections. They are efficient vectors for human infection because they feed on blood from both people and domestic reservoir mammals (dogs, cats, guinea pigs), reproduce prolifically while co-habiting close to people, and defecate soon after taking a blood meal. Infection rates in these vectors can be as high as 100% south of the Equator. Twelve species of triatomines are found in the United States. The most important are *Triatoma sanguisuga* in the eastern United States, *Triatoma gerstaeckeri* in Texas and New Mexico, and *Triatoma rubida* and *Triatoma protracta* in Arizona and California.^{25,65} In comparison, infection rates of the two principal vectors in the United States, *T. protracta* and *T. sanguisuga*, are 20%. These two vectors are peridomestic, and their inability to adapt to living in human dwellings, their different feeding and defecation habits, and their lack of access to people with a higher standard of housing are some reasons for low infection rates in the United States. As a comparison, in Oklahoma, impounded or

Infectious Diseases of the Dog and Cat, 3rd Edition

owned dogs had 3.6% rate for positive antibody titer results, while those in rural areas of Argentina have had seropositive result rates as 65%.³⁵

The principal sylvan reservoir hosts of *T. cruzi* in the southern United States are opossums, raccoons, and armadillos.^{*} Similarly, in Maryland,¹¹⁶ Oklahoma,⁵⁶ North Carolina,⁶⁰ South Carolina,¹²³ and Georgia,^{93,94,123} raccoons and opossums are the main reservoir hosts. In California and New Mexico, the main sylvan hosts are various mouse, squirrel, and rat species.¹⁰ Although *T. cruzi* isolates from infected vectors, animal reservoirs, and people in North America show similar in vitro characteristics to those from South America,¹⁷ these isolates tend to be less pathogenic in mice than do South American isolates.¹⁵ Because inoculation of *T. cruzi* isolates from opossums and armadillos into dogs experimentally produces a similar disease described in naturally acquired cases of acute and chronic canine trypanosomiasis, dogs in nature are likely infected with the same isolates as are these sylvan hosts.²⁰⁻²²

* References: 10, 23, 30, 106, 110.

* References: 15, 16, 32, 60, 77, 84, 124.

72.1.2.2 *T. evansi* Infection

T. evansi, a previously recognized African trypanosome, was isolated from coati (*Nasua nasua*), horses, and dogs in the Pantanal region of Brazil.⁹⁵ *T. evansi* has one of the widest geographic distributions and mammalian host ranges of any trypanosome and is thought to have evolved from *Trypanosoma brucei*. When inoculated into rats, the isolates had a varied virulence and fluctuating parasitemia typical of the African trypanosomes. The data suggest that the organism is transmitted between domestic and sylvatic hosts in the region via as yet undetermined vectors. For a further discussion of *T. evansi* infection, see African Trypanosomiasis later in this chapter.

72.1.3 Pathogenesis

T. cruzi trypomastigotes enter host cells soon after infection, multiply unhindered, avoid the immune response, and are transported throughout the body primarily within macrophages. Parasitemia develops within a few days and peaks 2 to 3 weeks postinoculation (PI), coinciding with acute clinical disease.²⁰ The pathogenesis of the acute phase is thought to result from cell damage as trypomastigotes rupture from host cells, especially cardiac myocytes and in some cases neurologic tissue. Most clinical signs during the acute stage are referable to this cell destruction. The period from infection to development of acute disease is variable, with puppies showing severe disease 2 weeks PI. Dogs infected after age 6 months may show no signs of acute disease other than slight depression and low-rising parasitemia. In contrast to these events, some *T. cruzi* isolates that infect dogs in the United States are not pathogenic but can produce a marked serologic response and a low parasitemia during times of stress or immunosuppression.

Generally, by 4 weeks PI, parasitemias in infected dogs have dropped to undetectable levels probably the result of a rising specific immune response to the parasite, and signs of acute disease diminish. Dogs tend to remain asymptomatic for months or years. During this time, a progressive development of myocardial degeneration occurs, leading eventually to biventricular dilative cardiomyopathy of unknown pathogenesis.³ Many theories have been offered concerning the cause of the cardiomyopathy, including damage by toxic parasite products and immune-mediated mechanisms leading to autonomic nervous system disruption within the myocardium.^{53,69} Further studies suggest that local spasm of the coronary microvasculature will lead eventually

Infectious Diseases of the Dog and Cat, 3rd Edition

to myocardial ischemia and possibly to progressive cardiac myocyte destruction.¹² Infected human patients with progressive myocardial disease develop alterations in the conduction system and gradual cardiac insufficiency caused by mononuclear cell infiltration, microvascular alterations, ventricular remodeling, and fibrosis. Cardiac dilatation occurs when fibrosis no longer permits efficient compensatory hypertrophy.^{1,108} As a possible explanation, people with cardiomyopathy have had high levels of transforming growth factor (TGF)- β 1 in association with cardiomyopathy, intracellular activation of the TGF- β 1 pathway, and tissue fibrosis.⁸

Benzimidazole (BZ) compounds, used to treat *T. cruzi* infections, have their greatest efficacy during the acute rather than the chronic stage of infection. Furthermore, the efficacy of chemotherapy in clearing *T. cruzi* infection appears dependent on an adequately functioning immune system. In experimental infections in knockout mice with various cytokine deficiencies, the presence of interferon- γ and other cytokines was critical in determining the efficacy of BZ treatment.⁹⁹

Infectious Diseases of the Dog and Cat, 3rd Edition

72.1.4 Clinical Findings

72.1.4.1 Dogs

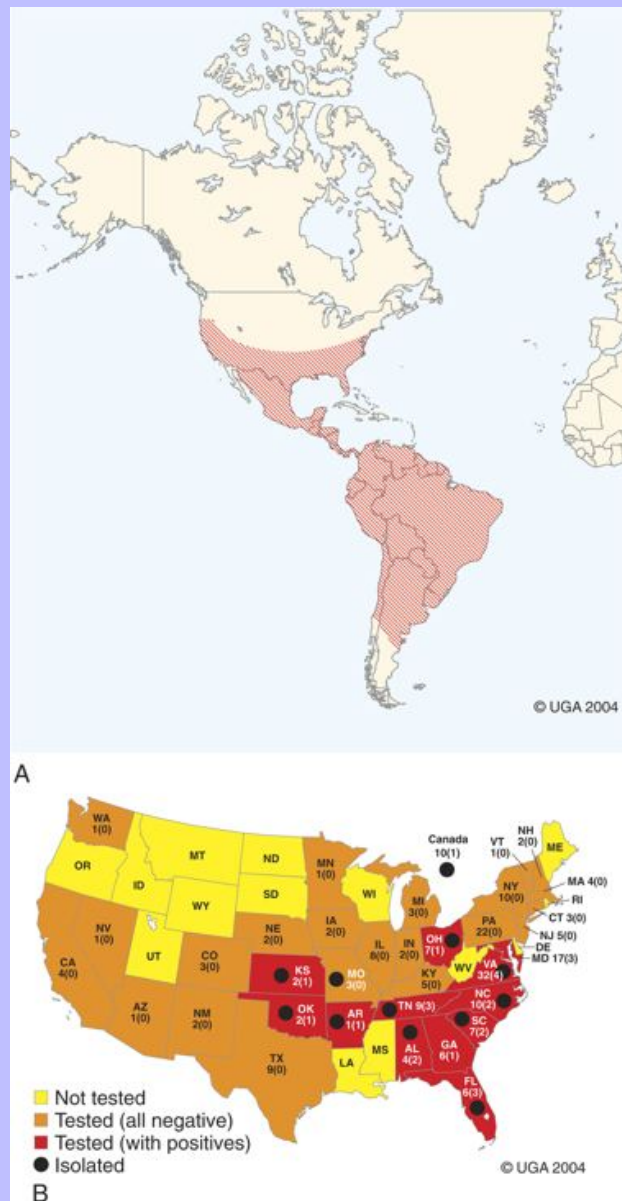

Clinically affected dogs develop either acute or chronic disease. Acute disease occurs mainly in dogs younger than 1 year of age and is sudden in onset, with signs referable to right-sided heart failure and cardiac arrhythmias. Generalized lymphadenomegaly may precede and is invariably present during acute illness. Signs referable to acute myocarditis, such as sudden collapse and death of a previously normal young dog, have been reported most frequently. Pale mucous membranes, slowed capillary refill time, weak pulse with deficits, tachyarrhythmia, and terminal hypothermia and respiratory distress are common. Most infected dogs that do not die suddenly develop ascites, hepatomegaly, and splenomegaly caused by right-sided heart failure. Anorexia and diarrhea are also common during acute disease. Neurologic signs referable to meningoencephalitis, including pelvic limb ataxia, profound weakness, and hyperreflexive spinal reflexes suggestive of distemper, have been found in naturally and experimentally infected dogs.^{10,20,26} During acute disease, dogs, similar to experimentally infected mice, probably suffer a profound immunosuppression because of altered interleukin-2 activity.¹⁰⁸ Such immunosuppression has been proposed as the cause of the development of distemper in pups with acute canine trypanosomiasis after they received modified live distemper vaccine.²⁴ Electrocardiographic (ECG) changes during acute disease are highly variable and include alteration in ST-T segments, T-wave inversion, low-amplitude QRS complexes, positive polyphasic ventricular premature contractions, and first- and second-degree heart block.²¹

Infectious Diseases of the Dog and Cat, 3rd Edition

Survivors of acute myocarditis will become aparasitemic and asymptomatic, and they develop chronic myocarditis with cardiac dilatation over the next 8 to 36 months.^{20,21} During the long asymptomatic period between acute and chronic disease in the dog, ECG readings may be normal except for the intermittent occurrence of ventricular arrhythmias, which can be exacerbated by exercise or excitement.¹¹ Sudden death during this stage can occur and is thought to be caused by fatal cardiac arrhythmias. As cardiac dilatation occurs, ECG abnormalities become more prevalent, and clinical signs referable to right-sided and eventually, in some cases, left-sided chamber failure occur. Dogs diagnosed at an older age (mean of 9 years) survived between 30 to 60 months, whereas dogs diagnosed at a younger age (mean of 4.5 years) survived only up to 5 months postdiagnosis.⁷⁸ These cases are indistinguishable from chronic dilative cardiomyopathy seen in large breeds of dogs and are often diagnosed as such until histology or immunohistochemical findings are available.²²⁻²⁴ Trypanosomiasis should be considered in any dog with signs of myocarditis or cardiomyopathy.

Megaesophagus and other megaviscus syndromes described in people with chronic Chagas' disease have not been described in dogs spontaneously or experimentally infected with *T. cruzi*. Morphometry of the myenteric esophagus was not altered in dogs with experimentally induced chronic *T. cruzi* infection.⁷⁰

72.1.4.2 Cats

Cats are reported to be susceptible to South American isolates of *T. cruzi*, but little information is available regarding clinical disease. No reports of domestic feline trypanosomiasis from North America have been submitted.

72.1.5 Diagnosis

72.1.5.1 Radiographic and Clinical Laboratory Findings

Thoracic radiography is of value in the diagnosis of pleural effusion, pulmonary edema, and chamber dilation in both acute and chronic myocarditis. ECG information is valuable in the diagnosis of the dilative cardiomyopathy of chronic disease. Thinning of ventricular walls, large end-diastolic volumes, and low shortening fractions (usually under 20%) are often present.²¹

Hematology is of little specific diagnostic value. Lymphocytosis may occur in the acute phase in a small number of cases. Alanine aminotransferase activity may be elevated as a result of hepatic hypoxia. Creatine kinase (CK) and lactate dehydrogenase activities are rarely elevated during acute disease. Elevations of serum CK (isoenzyme MB) do occur but are too variable and transient to be of any diagnostic value in the dog.²⁰ The abdominal effusion is typically a modified transudate from cardiac causes.

72.1.5.2 Cytology

Trypomastigotes can be identified in the blood just before and during acute disease (see Fig. 72-1). Although organisms are identified in most cases of acute trypanosomiasis, rarely are they found in chronic cases.

Parasitemias are often so low, however, that organisms can be missed during routine examination of Wright-stained blood films. Trypomastigotes may be pelleted for examination from plasma (obtained by centrifugation of 50 ml of heparinized blood at $800 \times G$ for 10 minutes) by further centrifugation ($8000 \times G$

679
680

Infectious Diseases of the Dog and Cat, 3rd Edition

for 15 minutes). High-power (400×) examination of the buffy coat-plasma interface of a centrifuged microhematocrit tube may reveal characteristically motile parasites. A thick-film buffy coat smear, stained with Wright's or Giemsa stain or examined as a wet preparation for trypomastigote movement, is also an effective means of concentrating trypomastigotes. Lymph node aspirates or impression smears may be positive even when parasitemias are very low. Abdominal effusions may contain organisms that can be identified cytologically. Polymerase chain reaction (PCR) has been shown to have higher sensitivity than microscopic methods in detecting parasitemia.⁶³

72.1.5.3 Isolation

Isolation of organisms into germ-free hosts or cell culture systems is a sensitive but time-consuming practice. Blood agar slants overlaid with liver infusion tryptose (LIT) medium or LIT alone are effective for isolating trypomastigotes from blood of an infected animal, but from 2 to 20 weeks may be needed for the results to become positive for epimastigotes.⁶⁶ Direct inoculation of blood into a Vero cell monolayer will usually result in the development of intracellular amastigote forms and trypomastigotes in media after 2 to 4 weeks.

Weanling laboratory inbred mice (C3H) inoculated intraperitoneally or subcutaneously with the patient's blood will usually develop detectable parasitemias 10 to 30 days later. Treating mice with glucocorticoids before and after inoculation increases the sensitivity.

72.1.5.4 Serologic and Polymerase Chain Reaction Testing

The indirect fluorescent antibody (FA) test, enzyme-linked immunosorbent assay (ELISA), and radioimmunoprecipitation assays are most commonly used.^{30,114} These tests confirm the presence of antibodies to *T. cruzi* but most cross-react with antibodies to *Leishmania*.⁴⁸ Positive titer results should be confirmed by additional testing for *Leishmania* to determine which has more seroreactivity. In an experimental infection in dogs, PCR, antibody testing, and xenodiagnostic methods were evaluated. The serologic testing results were positive in all dogs for parasite-specific antibody. A PCR assay with high specificity for *T. cruzi* had sensitivity ranging from 67% to 100% with more accuracy if multiple (2 to 9) serially collected samples were examined.⁷ However, xenodiagnostic methods only yielded positive results ranging between 11% to 22%. In a subset of people with myocardiopathic signs consistent with *T. cruzi* infection, serologic test results have been negative, despite positive results using PCR.¹⁰² This finding is a major concern with regard to diagnosis, therapeutic monitoring, and blood donor screening. Similar information is not available for dogs. Serologic testing for *T. cruzi*-specific antibodies in association with clinical signs is considered the gold standard for the diagnosis of Chagas' disease in dogs. Central laboratories in North America perform serologic assays for *T. cruzi* (see [Appendix 5](#)). Titer results usually become positive by 3 weeks PI at the time when parasitemias are declining and persist for the life of the animal.¹⁸ Because of the cross-reactivity with *Leishmania* spp., all positive sera results should be confirmed by also testing the sera for reactivity to *L. donovani*. The cross-reactive titer should be 1 to 2 dilutions less than the reactivity to *T. cruzi*.²⁵

72.1.6 Pathologic Findings

In acute disease, lesions usually are confined to the heart, especially the right side. Subendocardial and subepicardial hemorrhages, as well as multiple yellow to white myocardial spots and streaks, mainly involve the coronary groove.^{22,120} Hepatic, splenic, and renal congestion, as well as pulmonary edema, may be present

Infectious Diseases of the Dog and Cat, 3rd Edition

secondary to cardiac failure. Microscopically, a diffuse granulomatous inflammation, hydropic degeneration and necrosis of myofibrils, and a mononuclear cellular infiltrate typify acute cases. Numerous pseudocysts containing amastigotes are often associated with the inflammatory response (Fig. 72-4). Mild granulomatous myositis and organisms can be found in other organs, including the smooth muscle of the stomach, small intestine, bladder, and skeletal muscle. Nonsuppurative encephalitis has also been found.

Fig 72-4 Amastigotes in a pseudocyst within the cardiac muscle of a dog (H and E stain, $\times 1000$).

Chronic disease is characterized by a bilaterally enlarged flaccid heart with areas of thinning of the ventricular walls caused by fibrous plaques. Histologically, multifocal coalescing areas of lymphoplasmacytic inflammation and mild necrosis with extensive loss of myocardial fibers and replacement by fibrous tissue occur. Organisms are seldom found in tissues. The apex of the heart is one of the more likely areas to find them.²²

72.1.7 Therapy

Two drugs have shown some efficacy in the treatment of American trypanosomiasis (Table 72-1). The investigational drug nifurtimox (Bayer 2502 or Lampit, Bayer Ag, Leverkusen-Bayerwerk, Germany) has been reported to be successful in treating experimental and natural cases of canine trypanosomiasis, but severe side effects often preclude its use.⁵¹ Improved survival has been shown to occur in dogs treated concurrently with antiinflammatory doses of glucocorticoids.² Benznidazole (Ragonil®, Roche SA, Buenos Aires, Argentina) has been shown to produce cures in acute Chagas' disease in people and dogs and has less side effects compared with nifurtimox. Although neither drug shows any efficacy during the chronic stage of disease, benznidazole and nifurtimox are considered the recommended therapies for Chagas' disease.¹¹³ Both drugs are available in the United States from the Centers for Disease Control and Prevention, Atlanta, Georgia. Ketoconazole, gossypol, and allopurinol have been investigated, but the results of these studies are less than convincing.^{45,74,100} Albaconazole, an experimental triazole, was effective in suppressing parasite proliferation and death in infected dogs; however, a cure was not achieved.^{41a} The calcium channel blocker, verapamil,

Infectious Diseases of the Dog and Cat, 3rd Edition

decreases mortality in acutely infected mice⁸¹ and decreases the severity of cardiac pathology in chronically infected mice¹⁰⁹ but does not have the same efficacy in dogs with Chagas' disease.¹³ For further information on nifurtimox, see Drug Formulary, [Appendix 8](#).

680

Melarsoprol	2.2	IV	24	10

a See Drug Formulary, [Appendix 8](#), for additional information on each drug.

b Dose per administration at specified interval.

c Lampit (Bayer) is an investigational drug in the United States. Available only from the Centers for Disease Control and Prevention, Atlanta, Georgia, for treatment of human infections.

d Available for use in endemic areas.

e Repeat therapy as needed to control relapse or reinfection.

Supportive therapy, including furosemide and theophylline, is indicated in cases of dilatational myocarditis. Cardiac arrhythmias may require specific therapy, depending on the source and severity of the disturbance. If the disease is diagnosed and treated early enough, the mortality rate of acute disease can be decreased. However, dogs surviving acute disease invariably develop chronic cardiac disease in 1 to 5 years. The prognoses of these animals must be guarded because the outcome is usually fatal.

72.1.8 Prevention

Preventing contact between dogs and infected vectors by upgrading housing of the dogs will do much to limit infection. Residual insecticides should be sprayed monthly in peridomestic structures (woodpiles, chicken houses) and dog kennels. Oral cythioate (Proban, Bayer, Shawnee, Kan.), 3 mg/kg every other day, given to dogs housed outdoors will reduce vector numbers. Once vector numbers are reduced, the dose can be given twice a week. Limiting contact between dogs and infected reservoir hosts (opossums, raccoons, armadillos) and their vectors is virtually impossible but would limit infection. Most cases in the United States have been reported in hunting dogs, which do have an increased risk of exposure.¹⁹ Dogs should not be fed raw meat of reservoir hosts. Blood donors in endemic areas should be screened serologically to determine previous exposure to *T. cruzi*.

Persistent immunity does not develop in dogs infected with *T. cruzi*. Experimentally, dogs have been reinfected five times over a 3-year period.⁷¹ Levels of parasitemia decreased and antibody titers increased with each successive reinfection. Neither amastigotes nor *T. cruzi* DNA was detected in tissues of infected dogs after the fifth infection; however, progressive myocarditis was observed.

Infectious Diseases of the Dog and Cat, 3rd Edition

72.1.9 Public Health Considerations

An estimated 20 million Latin Americans are infected with Chagas' disease, but only three naturally acquired cases have been reported in the United States.⁸⁴ Several factors are probably responsible for this low prevalence of Chagas' disease. First, the North American species of *Triatoma* usually leave the host before defecating, unlike the South American insect, which defecates while still on the host. Because contact with infected insect feces is the usual mode of transmission in people, this behavior limits the chance of contact. Second, the density of infected *Triatoma* in human dwellings is much less in the United States than it is in endemic areas of South America. Third, more cases of human Chagas' disease may have occurred in the United States but have gone unrecognized because of a low index of suspicion. Because estimates are that 50,000 to 100,000 infected people now reside in the United States, the risk of catching *T. cruzi* from blood transfusion is greater than it is from infected vectors. Blood transfusion has been a major risk of infection for people in many Latin American countries.

Chagas' disease in dogs and wild hosts is of considerable public health significance because of the severity of and difficulty in treating the disease in people. Dogs cohabitating premises with people in endemic areas may serve as reservoir hosts for an insect species that is considered a zoonotic vector. Dogs diagnosed with this disease serve as sentinels for potential human infection and likelihood of infected bug infestation of a domicile.²⁵ Veterinarians should take particular care in treating animals with *T. cruzi* infection and make owners aware of the potential zoonotic risk. Blood samples taken from infected dogs are potentially infective, and laboratory staff should be appropriately instructed in handling suspected body fluids and tissues.

72.2 AFRICAN TRYPANOSOMIASIS

Craig E. Greene

George Matete

72.2.1 Etiology and Epidemiology

Trypanosomiasis is an important hemoparasitic disease of animals and people in Africa (i.e., sleeping sickness). Human infections occur in 36 African countries between 14 degrees North and 29 degrees South latitude (Fig. 72-5).⁷⁵ *T. brucei* comprises a group of indistinguishable flagellated hemoparasites in the subgenus *Trypanozoon*. Some of the subspecies cause human sleeping sickness. *T. brucei brucei* and *Trypanosoma congolense*, a species in the subgenus *Nannomonas*, are parasites of wild and domestic animals but do not infect people. Host species differ in their susceptibility to infection, and dogs are particularly susceptible to *T. congolense* and *T. brucei brucei*.⁹⁰ *T. evansi* is thought to have evolved from *T. brucei*.

Dogs are susceptible to various trypanosomes, including *T. brucei brucei*, *T. brucei rhodesiense*, *T. brucei gambiense*, *T. congolense*, and *T. evansi*.⁷⁵ In Nigeria, canine trypanosomiasis occurs in the *T. brucei gambiense* region causing ocular, lymphatic, and meningeal forms.⁸⁹ In Kenya, outbreaks of infection with *T. brucei rhodesiense* are associated with development of corresponding outbreaks of blindness in dogs and sleeping sickness in people.⁷⁵ Dogs may be more important as sentinels for infection rather than reservoir hosts. Dogs, which have a course of disease of 2 to 4 weeks until death, are unlikely to maintain the infection in nature.

Fig 72-5 Geographic distribution of African trypanosomiasis. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 72-6 Tsetse fly, the vector of African trypanosomiasis.

These parasites are transmitted by tsetse flies of the genus *Glossina*, which are widespread in Africa (Fig. 72-6). Transmission of infection in nature occurs primarily around water sources frequented by hosts and the vector flies. Mechanical transmission by other vectors and congenital transmission does not occur in nature. Rare laboratory inoculations have developed into disease.

In the cycle of infection, flies become infected after ingesting blood containing trypomastigotes (Fig. 72-7). The organism has a developmental cycle in the insect vector and transforms into slender trypomastigotes, which enter the salivary glands and become infective epimastigotes. Transmission occurs when these forms are inoculated by the fly during feeding on a new host.

72.2.2 Pathogenesis

Once they enter the mammalian host, African trypanosomes also replicate unimpeded by immune defenses. Unlike *T. cruzi*, African trypanosomes undergo continual antigenic variation of their outer glycoprotein coat as a means of immune evasion. Replication in the host results in widespread hemolymphatic dissemination. From the site of inoculation, inflammation spreads to the lymph nodes and spleen. Pericarditis and myocarditis, anemia, thrombocytopenia, leukocytosis, and disseminated intravascular coagulation can occur. Ocular involvement is thought to occur via the localization of organisms or associated immune complexes in the uveal tract with deposition along the inner surface of the cornea. Damage to the corneal endothelium, with resultant corneal edema, or granular deposits along the inner corneal surface may cause clouding of the cornea, similar to the “blue eye” observed in infectious canine hepatitis (see Chapter 4). Invasion of the central nervous system occurs in final stages of the disease with a diffuse meningoencephalitis.

The spleen is important in the production of antibodies and immune response to these hemoprotozoa. Splenectomy delays the onset of anemia and increases parasitemia and febrile responses.⁴²

72.2.3 Clinical Findings

Clinical signs in acutely infected dogs consist of anorexia and fever (mean, 39.8° C [102.2° F]); edema of the face, genitalia, and subcutaneous tissues; purulent ocular and nasal discharges; orchitis in male dogs; and pale mucosae and weakness. Petechial hemorrhage and mucosal bleeding, lymphadenomegaly, and splenomegaly also occur. Weight loss is typical of chronically infected animals. As in people, sleepiness is an apparent

Infectious Diseases of the Dog and Cat, 3rd Edition

feature, and it may relate to meningoencephalitis. In Nigeria, *T. brucei gambiense* infections are associated with ocular inflammation and lymphadenomegaly. In Kenya, ocular manifestations with *T. brucei brucei* and *T. brucei rhodesiense* predominate. Other clinical features, not previously described, include pale mucosae, dyspnea, rough haircoat, and subcutaneous edema of the head and neck.⁷⁵ The swelling of the thoracic limbs and neck has been associated with the development of decubital ulcers and limb edema caused by prolonged recumbency. Neurologic abnormalities include mental dullness and postural reaction deficits with intact reflexes, indicating upper motor neuron dysfunction. Neurologic signs are progressive and result in mental deterioration and behavioral changes similar to those of rabies. Ocular lesions include corneal opacity, conjunctivitis with a mucopurulent oculonasal discharge, uveitis with hemorrhage and turbidity in the anterior chamber, and visual loss (Fig. 72-8).⁷⁵

72.2.4 Diagnosis and Pathologic Findings

Hematologic changes during the course of infection include a decline in hematocrit with reticulocytosis and elevated mean corpuscular volume. The white blood cell count often decreases with neutropenia, lymphopenia, and eosinopenia and thrombocytopenia. In other cases, leukocytosis with neutrophilia has been noted. Trypanosomes may be demonstrated in the blood of infected dogs and in the cerebrospinal fluid (CSF) of those with neurologic signs (Fig. 72-9). CSF analysis changes are pleocytosis with a predominance of lymphocytes.

682

Fig 72-7 Life cycle of African trypanosomiasis. **A**, The organism is ingested by the insect vector as a trypomastigote in the blood. **B**, Within the vector midgut, the organism transforms into slender procyclic trypomastigotes that enter salivary glands. **C**, There, transformation takes place into epimastigotes, and **D**, subsequently to metacyclic trypomastigotes which are **(E)** inoculated into an uninfected susceptible host during feeding. (Courtesy University of Georgia, Athens, Ga.)

Fig 72-8 Corneal opacity in a dog with naturally acquired African trypanosomiasis.

Immunodiagnostic methods include detection of an antibody response using indirect FA and ELISA methods, of which the latter is more sensitive. Trypanosome species-specific monoclonal antibodies have been used to detect circulating antigen in infected dogs.⁴³ The parasitemia of dogs infected with *T. evansi* was characterized by an undulating parasitemia.⁶ The end of the 2-week prepatent period correlated with an increase in serum antibody titer results that were not protective.

Genetic detection methods are being studied as a way to determine carriers of infection. The organism expresses a 743 bp molecular mass gene product that allows the organism to survive within the blood of human hosts.¹¹⁷ A unique serum resistance-associated (SRA) gene is found in *T. brucei rhodesiense* isolates, allowing the detection of this pathogen in the mammalian host and in tsetse vectors without the need for strain characterization of this species.⁸⁶ This SRA gene has been found in trypanosomes infecting a dog, which suggests that dogs may carry trypanosomes that infect people.⁷⁵

At necropsy, edema and subcutaneous hemorrhages may be visible in many organs. Hepatosplenomegaly and lymphadenomegaly may be apparent. The carcass is often emaciated, with edema of the face, ventral thorax, abdomen, and extremities. The mucopurulent exudate mats the hairs surrounding the eyes. Skeletal muscles show various degree of atrophy. The pericardial sac may be filled with turbid fluid, which may contain flakes of fibrin. Lymphoplasmacytic infiltrates are found in many organs. Throughout various regions in the central nervous system, cellular infiltration of the leptomeninges with macrophages, neutrophils, plasma cells, and lymphocytes is apparent.

72.2.5 Therapy

Few drugs exist in the treatment of African trypanosomiasis (see [Table 72-1](#)). Isometamidium chloride was the first drug used. Suramin is the drug of choice for treating East African trypanosomiasis in people who do not have neurologic manifestations. For meningoencephalitis, the trivalent arsenical Melarsoprol® (Melarsen,

Infectious Diseases of the Dog and Cat, 3rd Edition

France) is used. Melarsoprol® is effective in penetrating the nervous system but is available only on an experimental basis. Treatment of one dog with Melarsoprol® caused clearing of organisms in the blood within 24 hours and progressive clearing of the uveal inflammation.⁷⁵ However, the neurologic signs eventually progressed and the organism was found in impression smears of brain tissue at necropsy. Eflornithine is used to treat West African disease involving the central nervous system. Other arsenicals such as cymelarsan (RM 110, Merial, Iselin, N.J.) and an enzyme inhibitor, difluoromethylornithine (DFMO; Hoechst Marion-Roussel, Somerville, N.J.), have shown efficacy in experimental studies.^{90,107} DFMO has been combined with diminazene in treating infected dogs. Although relapses have occurred with this combination, they were lower than those that developed with either drug alone. Trypanosomes may cross the blood-brain barrier, evading the effective drugs, which are molecularly too large to cross.³⁸ Diminazene appears to be the most effective drug against relapses and is available for treatment of affected cattle. Concentrations of diminazene are higher in brain tissue of infected dogs compared with healthy dogs,^{90,91} presumably as a result of inflammation of the blood-brain barrier. Appropriate dosages for some of the previously listed drugs are listed in [Table 72-1](#). Further information on their use appears in the Drug Formulary, [Appendix 8](#).

Fig 72-9 Trypomastigotes in the blood of a dog with African trypanosomiasis. (From Gardiner CH, Fayer R, Dubey JP, et al. 1988. An atlas of protozoan parasites in animal tissues, USDA Agricultural Handbook No 651, Beltsville, Md.)

72.2.6 Public Health Considerations

Sleeping sickness is an endemic disease of sub-Saharan Africa caused by *T. brucei rhodesiense* in East Africa and *T. brucei gambiense* in West Africa. Following the bite of a tsetse fly, people develop fever, lethargy, rash, headache, gastrointestinal signs, neurologic signs, and myalgia. A local chancre at the site of the bite, lymphadenomegaly, splenomegaly, and signs of renal or cardiovascular dysfunction may also be observed. Laboratory abnormalities include leukopenia, anemia, thrombocytopenia, elevated hepatic transaminases,

Infectious Diseases of the Dog and Cat, 3rd Edition

coagulation abnormalities, azotemia, and hyponatremia.¹⁰⁵ Definitive diagnosis relies on demonstrating the organism in peripheral blood, CSF, or the inoculating wound site. Examination of lymph node aspirates is not as helpful. Early treatment with suramin prevents the more resistant meningoencephalitic form of the disease. Animals pose minimal risk for human infection. Rather, they act as sentinels for the same infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

73 CHAPTER 73 Leishmaniasis

The leishmaniasis are a group of infectious diseases that affect people and domestic and wild animals worldwide and are caused by members of the genus *Leishmania*. The infection is transmitted by sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World. Visceral leishmaniasis, the most severe disease form, is a frequent cause of clinical illness in dogs in some regions but is less common in cats. Reservoir hosts vary within different geographic areas and can include domestic or wild animals. Infected domestic dogs serve as reservoirs of the disease for people in several areas where leishmaniasis is endemic. Dogs are reservoirs for *Leishmania infantum* infection in an area that stretches from Portugal to China. They are also reservoirs of infection for foxes and opossums in an area of *Leishmania chagasi* (*infantum*) that extends from southern Mexico to South America. Canine leishmaniasis is also sometimes found in nonendemic countries because of international tourists and immigrants who bring infected pets or because of dog importation. Dogs can be asymptomatic carriers of leishmaniasis that are infectious to sandflies, and infection may go unnoticed for a long time. In this chapter, a global coverage of leishmaniasis will be presented, followed by two recognized geographic forms of emerging disease in animals in the New World.

73.1 LEISHMANIASIS

Gad Baneth

73.1.1 Etiology

Leishmaniasis is caused by diphasic protozoans of the genus *Leishmania* in the class Kinetoplasta and family Trypanosomatidae. About 30 different leishmanial species are found in various parts of the Old World and New World (Fig. 73-1). Of these, about 20 are responsible for a wide spectrum of clinical illnesses in people.¹⁵ Most *Leishmania* spp. that infect people are zoonotic, and only a few are strictly *anthroponotic* (i.e., transmitted directly from person to person via sandflies). Leishmaniasis is endemic in 88 countries—66 in the Old World and 22 in the New World. Approximately 12 million people are infected with leishmaniasis, and some 350 million people are at risk of acquiring the disease, with a yearly incidence of 1 to 1.5 million new cases of cutaneous disease and 500,000 new cases of the potentially fatal visceral form.^{55,56} Dogs are frequently involved in sylvan and urban cycles of zoonotic *Leishmania* spp. that cause disease in people in many parts of the world.²¹⁷ Based on seroprevalence studies from Spain, France, Italy, and Portugal, it has been estimated that 2.5 million dogs in these countries are infected with visceral leishmaniasis.¹⁴² The number of infected dogs in South America is also estimated to be in the millions, with high infection rates being reported in some areas of Brazil.

The genus *Leishmania* is divided into the subgenera *Leishmania* and *Viannia* based on the differences in sandfly development. Many species are recognized within these subgenera. Classification is primarily based on DNA sequence comparisons, electrophoresis migration patterns of isoenzymes (zymodemes), and reactivity to monoclonal antibodies and to membrane-shed antigens.

The diseases caused by the various *Leishmania* spp. in people are divided into three forms according to their clinical manifestations (Table 73-1): cutaneous leishmaniasis (CL), mucocutaneous leishmaniasis (MCL), and visceral leishmaniasis (VL). Some species cause more than one form of the disease.

Infectious Diseases of the Dog and Cat, 3rd Edition

Canine leishmaniasis is often classified as VL because it is associated with some of the *Leishmania* spp. that cause VL in people; however, dogs usually have visceral and cutaneous involvement. *L. chagasi*, the VL agent in South America, is considered to be synonymous with *L. infantum* based on various genetic analyses.¹³⁵ The low genetic variability of *L. chagasi* is consistent with recent importation to the New World, and it is thought that it was introduced by infected dogs from Europe that arrived with settlers.

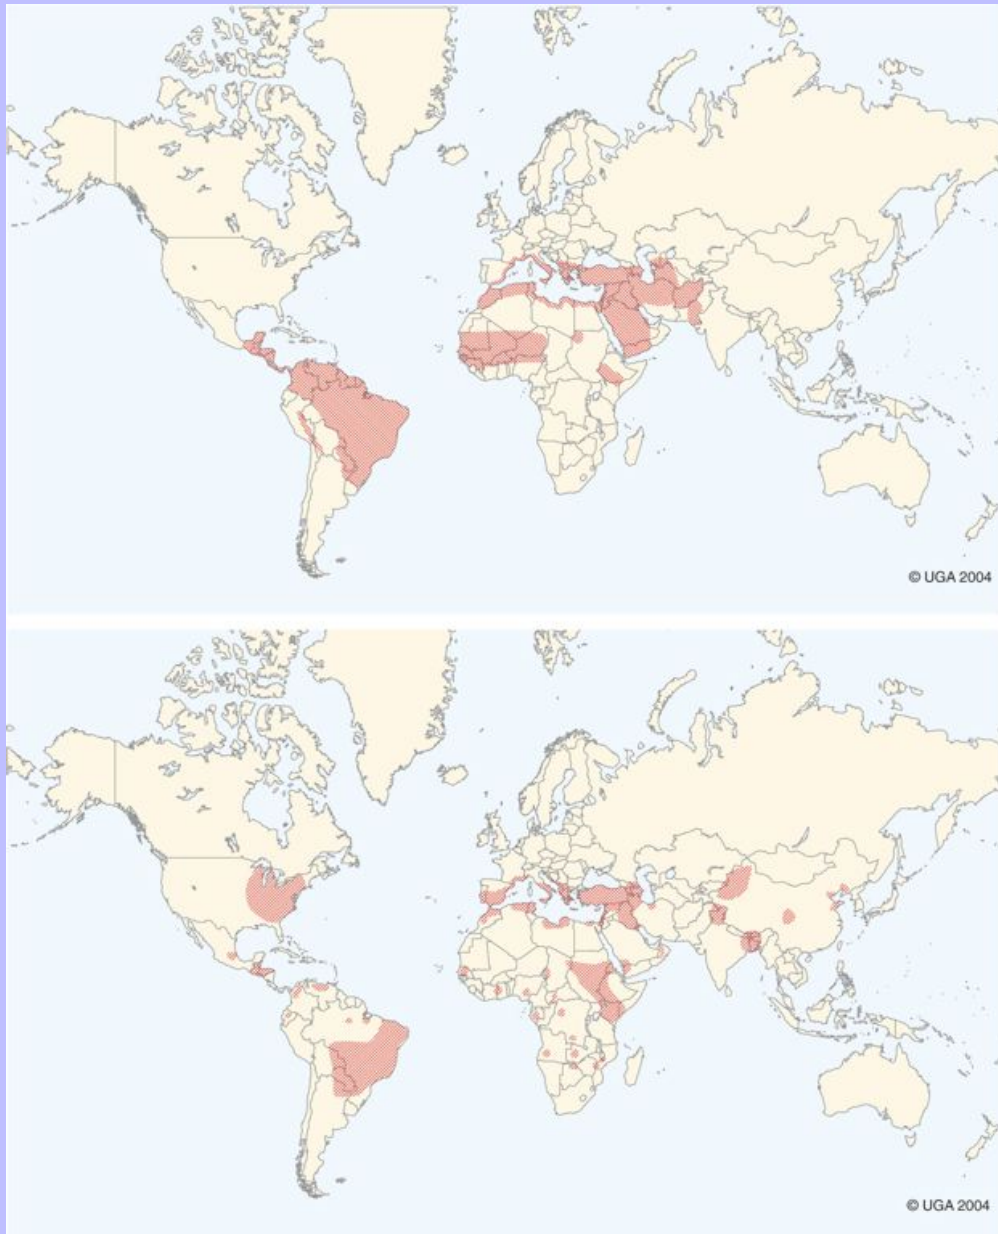

73.1.2 Epidemiology

The natural cycle of *Leishmania* infection involves a sandfly vector and a vertebrate host in which different forms of the parasite are found. Hematophagous female sandflies harbor *Leishmania* promastigotes in their guts and transmit the parasite during a blood meal to wild or domestic animals and people, where the amastigote form develops. Phlebotomine sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World are the natural vectors of leishmaniasis. Sandflies are small insects with a body length seldom exceeding 3 mm.¹⁰⁵ The biting activity of sandflies is crepuscular and nocturnal. In the Mediterranean region and Asia, sandflies are primarily active in the warm months—from spring to late fall. In Latin America, some sandflies are active throughout the year. They do not move long distances, and studies have shown that they are seldom dispersed more than 1 km from their breeding sites. Many species of sandfly exist, but only some of them act as disease vectors. Different vector species may be found in distinct geographic regions and ecologic niches. Some sandfly species exclusively transmit only one *Leishmania* species, whereas others are vectors for more than one species. The vectorial capacity of different sandfly species appears to be related to the ability of promastigotes to specifically bind to receptors in the sandfly gut. When they do not bind to the sandfly gut, the parasites that initially replicated in the gut lumen are excreted with the sandfly feces and presumably do not reach the critical mass needed to infect a host during a second blood meal. Organisms of the *Viannia* subgenus of *Leishmania* *braziliensis* replicate in the hindgut, in contrast to the midgut replication characteristic of all other *Leishmania* species.

Infectious Diseases of the Dog and Cat, 3rd Edition

In vertebrate hosts, *Leishmania* is found in macrophages in its nonflagellate form, the amastigote. Amastigotes are ovoid or round, 2.5 to 5 µm long and 1.5 to 2 µm wide. In addition to a basophilic-staining nucleus, a rod-shape, darker staining kinetoplast is visible with Wright's or Giemsa stain (Fig. 73-2). Amastigotes multiply by binary fission, rupture out of the macrophage, and infect new cells. Sandflies can ingest the amastigotes when they become engorged with blood from an infected host. In the sandfly, amastigotes are freed from their host cells, undergo a series of morphologic alterations, transform into the extracellular flagellated promastigote form, and replicate in the sandfly gut (Fig. 73-3). Promastigotes are injected with saliva into the skin of a vertebrate host when the female feeds again. After inoculation into the host, the promastigotes lose their flagella and transform back into amastigotes (Fig. 73-4).

d Causative agents of American tegumentary leishmaniasis in dogs in South or Central America.

Fig 73-2 *L. infantum* amastigotes in canine macrophage from popliteal lymph node aspirate (May-Grunwald-Giemsa stain, ×500).

Domestic dogs (*Canis familiaris*) are considered the main VL reservoirs for people in the Mediterranean basin, Middle East, and South America, where *L. infantum* (*L. chagasi*) is the causative agent of infection. In regions with a high infection rate among dogs, the incidence of clinical VL in the general human population is generally low²¹⁷; however, human exposure rates (as determined by the prevalence of specific antibodies or positive leishmanin skin test results), which indicate past exposure to *Leishmania* organisms, may be high.^{2,4,141,216} In the Indian subcontinent and East Africa, where *Leishmania donovani* is the agent of VL, people are the reservoir hosts, and animals do not appear to play a significant role in the anthroponotic epidemiology of infection. The main reservoir hosts for *Leishmania* spp. causing CL and MCL in people are rodents and other wild animal species. Domestic cats are rarely hosts.

Fig 73-3 *Leishmania* promastigotes grown in culture. Note round nuclei and rod-shape kinetoplast (May-Grunwald-Giemsa stain, ×1000).

Infectious Diseases of the Dog and Cat, 3rd Edition

Canine VL caused by *L. infantum* is an important cause of zoonotic disease in many endemic countries and areas, including Spain, Portugal, southern France, Italy, Malta, Greece, Turkey, Israel, Egypt, Tunisia, Algeria, Morocco, Iraq, Iran, the former Asian republics of the Union of the Soviet Socialist Republics, Pakistan, and some parts of China.^{18,131,137,170,208} Recent information indicates that VL may occur also in a part of southern

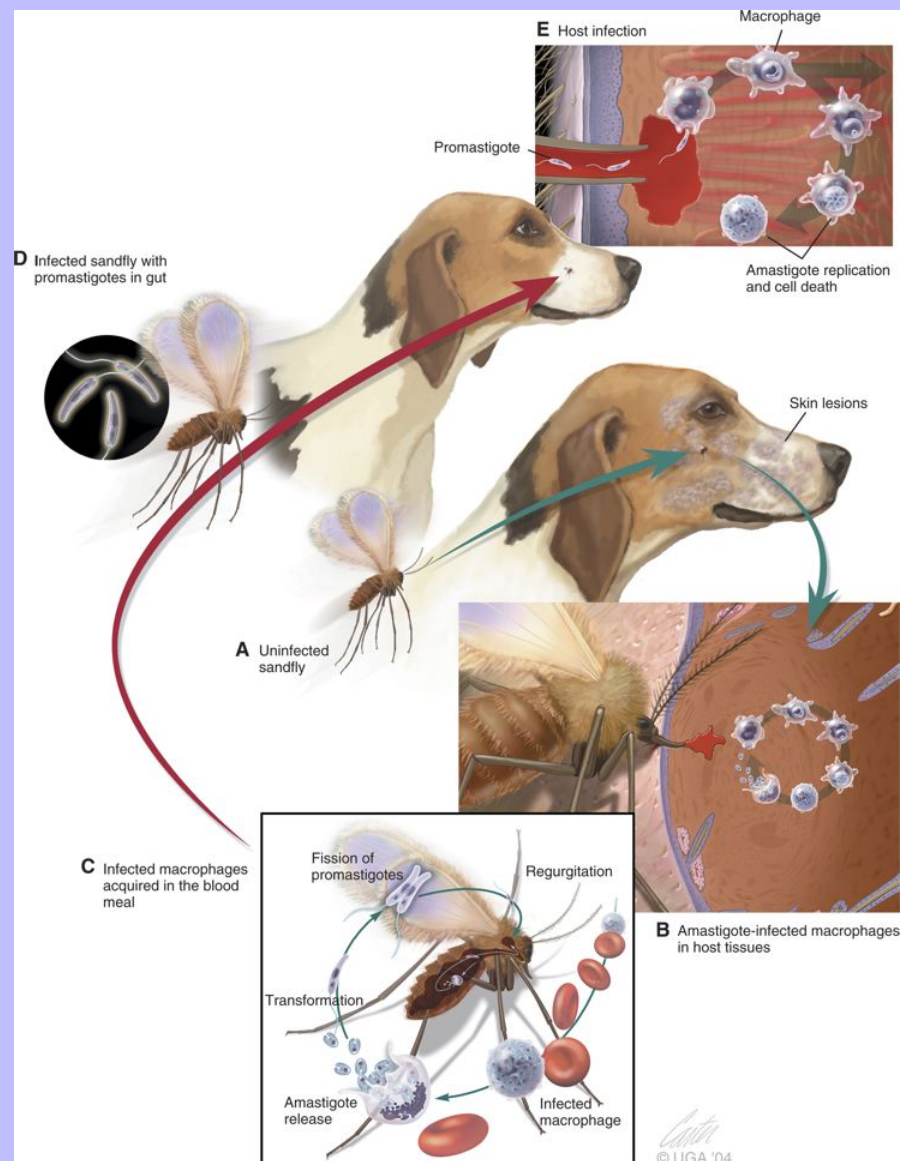

Germany.¹¹² Reports have been made of sporadic cases of canine leishmaniasis caused by importation or 687

transport of infected dogs to countries where sandfly transmission of VL does not occur, such as Holland, 689

England, and Sweden.²⁰⁶ Similarly, dogs are a reservoir of *L. infantum* (*L. chagasi*) infection for people in South America.⁴¹ Because many dogs in endemic areas harbor asymptomatic infections, infection rates are often estimated not only by the presence of clinical signs compatible with the disease, but also by serologic methods, the presence of parasite DNA in the tissues or blood, or both as determined by the polymerase chain reaction (PCR). Canine infection rates as shown by PCR and serology in highly endemic foci such as the Balearic Islands of Spain,¹⁹⁹ the Marseille area in France,²⁶ and Greece¹¹⁸ approach 70% to 80%. This is a much higher prevalence of infection than that associated with symptomatic disease or determined by serology alone. It is thought that most or all dogs in these areas are infected during their lives. Some dogs succumb to the infection, others harbor the pathogen and are resistant to the development of clinical disease, and some dogs are able to eliminate the pathogen before developing clinical disease. In other areas, infection is not as highly prevalent, possibly because of less favorable environmental conditions for transmission and vectors.^{142,221}

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 73-4 The life cycle of *L. infantum*. **A**, Uninfected sandfly feeds on an infected host and **(B)** ingests infected macrophages in host tissues. **C**, The organisms are released from the infected macrophages into the sandfly gut and **(D)** transform into motile promastigotes which replicate in the sandfly gut. **E**, The promastigotes are regurgitated during feeding of the infected sandfly. The infected sandfly transmits the infection to the new host during feeding. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Canine infection occurs mostly in rural areas or the outskirts of towns; however, urbanization of canine and human infection has been reported and poses a threat to the well-being of large dogs and humans.^{49,142} *L. infantum* infection has been reported in wild canids such as foxes (*Vulpes vulpes*) and jackals (*Canis aureus*) in Europe and the Middle East and in crab-eating foxes (*Cerdocyon thous*) in South America.^{*} These wild canine species may demonstrate signs of disease or be asymptomatic. Infected crab-eating foxes were found to have low rates of transmission to the sandfly *Lutzomyia longipalpis* and were therefore not considered important as reservoirs of VL in Brazil.⁴⁵ The particular role of wild canids in the epidemiology and spread of sylvatic *L. infantum* infection to domestic dogs (*Canis familiaris*) and people is not well understood and should be separately investigated in every ecosystem where this disease is found. Although *L. infantum* is naturally transmitted through the bites of sandflies, vertical in utero transmission from a dam to its offspring has been documented in a few reports.⁵⁸ *Rhipicephalus sanguineus* has been shown to acquire *Leishmania* organism in their guts after feeding on infected dogs^{40a}; however, its competence as a vector has not been confirmed.

Leishmania tropica occurs in the Old World and is a rare cause of infection in dogs. *L. tropica* is an important agent of CL in people in some parts of the Middle East and Africa. It also caused VL in American soldiers returning from the Persian Gulf after the 1991 Operation Desert Storm¹²⁴ and in patients from India.¹⁷⁹ It has been sporadically found in dogs with CL from Tunisia and Morocco⁵⁴ and from another dog from Morocco with VL and no dermal abnormalities.⁹² However, *L. tropica* infection is rare compared with the common canine *L. infantum* infection.

* References 1, 18, 43, 47, 97, 125, 190.

73.1.3 Pathogenesis

As the sandfly bites, *Leishmania* promastigotes are transferred with the sandfly saliva into the vertebrate host's skin. The promastigotes are then phagocytized by macrophages and multiply as amastigotes within phagolysosomes that separate them from the host cell defense mechanisms. When the macrophage ruptures, freed amastigotes penetrate additional host cells and disseminate from the local bite site. They travel throughout the host's body but primarily to the hemolymphatic system organs and remote dermal areas to create a generalized infection.

As mentioned previously, not every dog naturally or experimentally infected with *Leishmania* develops disease.^{107,162} The immune responses mounted by dogs at the time of infection and thereafter appear to be the most important factor in determining whether they develop a generalized infection and whether and when the infection will progress from a asymptomatic state into symptomatic disease. Infection initially has no apparent symptoms but later might progress into a symptomatic disease unless the replication of amastigotes is halted by immune mechanisms. Dogs that are able to resist an infection by either resolving it and eliminating the parasite or restricting the infection and remaining consistently asymptomatic are *clinically resistant*. Animals that are predisposed to developing an infection and symptomatic disease are considered *susceptible*. The innate, or nonspecific, immune response is the first line of defense encountered by *Leishmania* parasites when entering the susceptible host. One of several suggested mechanisms by which *Leishmania* parasites depress the innate host immune defenses involves the ability of amastigotes to survive and replicate within macrophage phagolysosomes by producing compounds such as lypophosphoglycans that inhibit phagosome maturation.¹⁸⁰

Specific immune responses play a major role in susceptibility to infection. An experimental model of cutaneous leishmaniasis in mice infected with *Leishmania major* has shown that a susceptible mouse strain, which

Infectious Diseases of the Dog and Cat, 3rd Edition

typically develops a T-helper (Th) type 2 (Th2) cellular response, succumbed to infection. This Th2 response resulted in secretion of specific cytokines such as interleukin-4 (IL)-4 and interleukin-10 (IL)-10 and production of a significant antibody response. Other mouse strains that respond with a different set of cytokines, including interferon- γ (IFN- γ) and interleukin-12 (IL)-12, typical of a Th1 response are resistant to infection.^{93,187} IFN- γ secreted from T cells activates macrophages for the elimination of parasites. This general concept derived from the experimental CL model of a Th-cell dichotomy—in which one type of Th-cell response produces resistance or cure and a second type produces susceptibility and disease exacerbation—has been applied to infections with other pathogens in many hosts. However, whether this concept applies to VL is unclear. In experimental murine VL, both types of responses develop,^{103,140} and it is the balance of the Th1/Th2 responses that is considered to be important in controlling parasite replication, disease progression, or a cure. The balance between the two types of cellular immune responses also appears to be important in natural canine and human VL.

Protective immunity to leishmaniasis in dogs is mediated by T cells.¹⁶² Resistance to experimental infection with *L. infantum* in dogs is associated with proliferation of peripheral blood lymphocytes, which produce IL-2, tumor necrosis factor, and IFN- α with parasite antigen-specific stimulation. In addition, *L. infantum*-infected macrophages are lysed in a histocompatibility complex-restricted manner by CD8⁺ cytotoxic T cells, CD4⁺ cytotoxic T cells, or both. These processes are suppressed in symptomatic dogs, in which T-cell proliferation with leishmanial antigen and antigen-specific IFN- γ production are depressed and a marked IgG response to the parasite ensues.^{51,133,162,163} A strong delayed-type hypersensitivity response with the leishmanin intradermal skin test indicative of a cell-mediated response to *Leishmania* infection is found in infection-resistant dogs that have been exposed to the parasite and is absent in highly symptomatic dogs.^{162,197,198} In addition, intracellular killing of the parasite by neutrophils and monocytes is impaired.³⁴ During the infection, dogs become increasingly immunosuppressed and develop lower CD4⁺ lymphocyte counts and experience a decrease in the CD4⁺/CD8⁺ ratio.^{32,143} This finding is commonly associated with retroviral diseases, such as the human immunodeficiency virus (HIV) in people and feline immunodeficiency virus (FIV) in cats, and is proportional to the degree of susceptibility to opportunistic pathogens. Moreover, it has been demonstrated that the infectiousness of dogs with leishmaniasis to sandflies increases proportionally with the decrease in CD4⁺ counts.⁹¹

689

690

Susceptibility and resistance to canine VL appear to have a genetic basis. The prevalence of overt VL among Ibizan hounds in the Balearic Islands is lower than among other breeds, and it has been shown that this breed mounts a predominantly cellular immune response against *L. infantum*.¹⁹⁸ A study on the polymorphism of the canine NRAMP1 gene, which encodes an iron transporter protein involved in the control of intraphagosomal replication of parasites and macrophage activation, has implied that susceptible dogs have mutations in this gene.⁷ A DLA class II DLA-DRB1 genotype, which is a dog major histocompatibility complex class II allele, has been linked to the risk of being infected in an endemic area in Brazil.¹⁶⁹

Canine VL is usually a chronic disease, and clinical signs of disease may develop 3 months to 7 years after infection. T-lymphocyte regions in the lymphoid organs become depleted, and antibody-producing B-cell regions proliferate. The proliferation of B lymphocytes, plasma cells, histiocytes, and macrophages results in generalized lymphadenomegaly, splenomegaly, and consistent hyperglobulinemia. The immunoglobulin response is usually massive; however, it is not a protective response and can eventually be detrimental. Autoantibodies that may be associated with the development of pathologic phenomena such as immune-mediated thrombocytopenia and anemia are also frequently produced. Another potential hazard of impaired T-cell regulation with exuberant B-cell activity is the generation of large amounts of circulating immune complexes (CICs).¹²¹ CIC deposition in the walls of blood vessels may cause vasculitis, polyarthritis,

Infectious Diseases of the Dog and Cat, 3rd Edition

uveitis, and glomerulonephritis. In dogs, CIC deposition in the kidneys eventually results in renal failure, which is the main cause of death of dogs with leishmaniasis. Systemic vasculitis may lead to local ischemia that causes visceral and cutaneous necrosis and, although rare, to nervous system involvement.^{77,168} CICs may also include cryoglobulins. These proteins may precipitate in the blood vessels of the extremities when exposed to cold and cause ischemic necrosis.¹⁹²

Canine leishmaniasis is most often associated with various skin lesions, which are generalized rather than local because *L. infantum* disseminates all over the body.¹⁶⁷ It may also be detected in healthy-looking skin and not necessarily in dermal lesions.¹⁹⁶ The more rare form of generalized nodular lesions (the nodular form of leishmaniasis) probably indicates that a dog mounted a less effective immune response than that associated with generalized alopecia.⁷² Although rare, skin lesions could be restricted to a few ulcerations or nodules.

Dogs with leishmaniasis may show signs of a hemorrhagic diathesis—primarily epistaxis. Histopathology of the nasal mucosa of 10 dogs with CL, three of which had a history of epistaxis, revealed that all 10 dogs had ulcerative and inflammatory lesions that could be involved with bleeding.¹⁰² Other than nasal ulcers, possible causes include paraglobulinemia, which may interfere with fibrin polymerization and which in association with uremia may inhibit thrombocyte function. In addition, thrombocytopenia may develop as a result of CIC, autoantibodies, splenic pooling, or bone marrow suppression. Anemia usually develops as a sequel to the decreased erythropoiesis of chronic disease or to chronic renal failure but may be aggravated by blood loss, an immune-based destruction of erythrocytes, or both.

73.1.4 Clinical Findings

73.1.4.1 Dogs

Canine VL is a chronic systemic disease. The signs of disease are highly variable and often begin with slight but progressive dullness and insidious exercise intolerance. The clinical findings in canine leishmaniasis are presented in [Table 73-2](#).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 73-2 Clinical Findings in 80 Dogs with Leishmaniasis¹⁹¹

Fig 73-5 Canine leishmaniasis showing exfoliative dermatitis and scaling on face.

Infectious Diseases of the Dog and Cat, 3rd Edition

The prevalence of cutaneous lesions in dogs with symptomatic leishmaniasis ranges between 56% to 90%.^{40,109,191} Dermatologic abnormalities may occur in the apparent absence of other obvious signs of disease, but any animal with dermal manifestations of leishmaniasis should be presumed to have visceral involvement, because the parasites disseminate throughout the body before generalized skin lesions develop. Dermatologic abnormalities vary in character and extent but are rarely pruritic. Most dogs develop a progressive and symmetric alopecia with exfoliative dermatitis and desquamation, usually commencing on the head and extending to the rest of the body (Fig. 73-5). In addition, some animals develop ulcerations on the nose and the pinna (Fig. 73-6) or chapping of the muzzle or the footpads. Less frequently, mucocutaneous ulcers (Fig. 73-7), cutaneous nodules, mucosal nodules, or pustular eruptions develop.^{78,109,111,71a} Lymphadenomegaly of multiple superficial lymph nodes frequently develops in canine VL^{119b} with lymph nodes enlarging 2 to 6 times their normal size and occasionally mimicking clinical findings of lymphosarcoma. Splenomegaly is also frequently detected by abdominal palpation.

690

691

Fig 73-6 Canine leishmaniasis showing scaling on pinna and face.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 73-7 Mucocutaneous ulceration in a dog with leishmaniasis.

Approximately 20% to 40% of the dogs diagnosed with VL have ocular lesions, including keratoconjunctivitis and lymphoplasmacytic or granulomatous uveitis (Fig. 73-8).^{40,80,160,191} In some cases, ocular abnormalities are the only clinical signs.¹⁶⁰ Abnormally long or brittle nails (onychogryphosis), a rather specific finding, develop in a small proportion of the patients. Epistaxis is another clinical sign that may develop in conjunction with other typical abnormalities or as the only presenting sign in canine VL (Fig. 73-9).¹⁰²

Fig 73-8 Ocular lesions in leishmaniasis showing conjunctivitis in a dog with uveitis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 73-9 Epistaxis in St. Bernard with leishmaniasis and no dermal lesions.

Fig 73-10 Dog with characteristic features of leishmaniasis. Note cachexia, muscle atrophy, and excessive scaling.

Weight loss and muscle atrophy are the most common signs of visceral involvement (Fig. 73-10). Some dogs lose weight despite having a ravenous appetite. A serious worsening of condition is often associated with ensuing renal failure. Progressive renal failure may be accompanied by anorexia, mental depression, polyuria, polydipsia, and vomiting. Transient diarrhea may occur. Renal failure may be the sole apparent abnormality in dogs with VL; dogs with this condition in endemic areas should be tested for leishmaniasis.

691

692

Infectious Diseases of the Dog and Cat, 3rd Edition

In cases of overt disease, decreased physical activity is obvious and related to somnolence, decreased endurance, and locomotion disturbances. Locomotion disturbances may be caused by neuralgia, polyarthritis, polymyositis, footpad clefts, interdigital ulcers, osteoarticular and osteolytic lesions, or proliferative periostitis.^{5,28,200b} Body rectal temperature may fluctuate but is usually normal or subfebrile. Immunosuppression may promote the occurrence of concomitant infections, hence the clinical picture may be complicated by conditions such as demodicosis, pyoderma, gastrointestinal disease, and pneumonia. Combined infections with *Ehrlichia*, *Babesia*, *Hepatozoon*, *Trypanosoma*, and *Dirofilaria* are quite common when *Leishmania* infection occurs in regions where these organisms are also endemic. Other less common manifestations may include pericardial tamponade,⁷⁵ masticatory myositis,²¹⁰ pancreatitis,³⁶ meningitis,²¹⁵ chronic colitis,⁶⁷ pemphigus,⁸³ and polyarthritis.²⁰¹ Thrombosis has also occurred as a result of the nephrotic syndrome caused by glomerulonephritis.^{72,74} Signs caused by disseminated intravascular coagulation or its complications may occur.⁷⁶

73.1.4.2

Cats

Feline leishmaniasis is rare. Symptomatic leishmaniasis in domestic cats have included infection with *L. infantum*,^{154,165,180a} *Leishmania mexicana*,^{20,46} *Leishmania venezuelensis*,^{29,30} *L. (Viannia) braziliensis*,¹⁸⁶ and unspecified species.⁹⁶

Sporadic cases of feline leishmaniasis in southern Europe caused by *L. infantum* have been described. The cats had cutaneous ulcerative or nodular lesions essentially similar to those found in dogs (Fig. 73-11).^{96,165,178a,160a} One cat had visceral involvement that included hepatosplenomegaly, icterus, lymphoplasmocytic gastroenteritis with abundant *Leishmania* parasites, and membranous glomerulonephritis.⁹⁶ A second cat from which *L. infantum* MON-1 zymodeme was cultured had disseminated crusty cutaneous lesions and amastigotes in the bone marrow.¹⁵⁴ Another cat with disseminated disease had uveitis as a predominant finding.^{119a} Infected cats were seropositive for *Leishmania* antigen by various serologic methods.^{96,154,165} Infection was reported in cats with feline leukemia virus and FIV¹⁶⁵ and also from cats with no retroviral disease.¹⁵⁴ Serologic or PCR surveys of cat populations in canine leishmaniasis-endemic regions in southern Europe indicate that feline infection might be more widespread than indicated by clinical manifestations.

Fig 73-11 Cutaneous ulcer in cat with leishmaniasis. (Courtesy Maria Grazia Pennisi, University of Messina, Messina, Italy.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Reports of feline leishmaniasis in the New World have primarily discussed cutaneous infections with species that cause CL in people. Pinnal nodules caused by *L. mexicana* were diagnosed in a cat from southern Texas.⁴⁶ Thirty months after radical pinnectomy was performed, the cat developed similar pinnal lesions that progressed to more diffuse lesions on the muzzle and in the nasal mucosa. No visceral organ involvement was found on necropsy.²⁰ Nodular lesions on the nose and ears have been observed in cats with CL in a *L. venezuelensis*-endemic region of Venezuela.²⁹ Infection with a dermatotropic *Leishmania* (*Viannia*) species in a cat from Brazil was detected in a proliferative interdigital lesion on the cat's posterior paw.¹⁵⁹ In other instances, *L. (V.) braziliensis* was isolated from cutaneous lesions from two cats in Brazil.^{186,200a} Experimental studies showed that cats were susceptible to a generally self-limiting infection with a human isolate of this organism.^{190a} *L. chagasi* DNA sequences were amplified from a lesion on a cat's nose; the cat was from a previously nonendemic area in Brazil.¹⁸¹

73.1.5 Diagnosis

73.1.5.1 Clinical Laboratory Findings

A summary of the clinicopathologic findings from three large case series studies on canine leishmaniasis^{40,110,191} is shown in Table 73-3. The most consistent serum biochemistry findings in dogs with clinical VL are serum hyperproteinemia with hyperglobulinemia and hypoalbuminemia resulting in a decreased albumin/globulin ratio. Marked hyperglobulinemia in dogs from *Leishmania*-endemic regions with no apparent cause or in dogs that have traveled to such areas should be investigated for VL. Mild increases of liver enzyme activities are frequent; however, grossly elevated liver enzyme activities, severe azotemia, or both are found in only a minority of dogs with VL. Proteinuria and some pathologic renal symptoms develop in most dogs with this disease, and subsequent renal failure caused by immune-complex glomerulonephritis eventually develops in dogs with progressive pathologic renal symptoms. The urinary protein/creatinine ratio and enzymuria have been proposed as tests for assessing renal damage in affected animals.^{156,157}

692

693

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 73-3 Clinicopathologic Abnormalities in Dogs with Visceral Leishmaniasis^{40,110,191}

ABNORMALITY	PERCENTAGE OF DOGS
Hyperproteinemia	63.3–72.8 ^{40,110}
Hyperglobulinemia	76–100 ^{40,191}
Hypoalbuminemia	68–94 ^{40,191}
Decreased albumin/globulin ratio	76 ⁴⁰
Azotemia	16–45 ^{40,191}
Increased serum alkaline phosphatase activity	16–51 ^{40,191}
Increased alanine aminotransferase activity	16–61 ^{40,191}
Proteinuria	71.5–85 ^{110,191}
Anemia	60–73.4 ^{110,191}
Leukocytosis	24 ⁴⁰
Leukopenia	22 ¹⁹¹
Thrombocytopenia	29.3–50 ^{40,191}
Positive for antinuclear antibody	31–53 ^{40,191}
Positive Coombs' test	21–84 ^{40,191}

Mild to moderate nonregenerative anemia is frequently found. More rarely, regenerative hemolytic anemia caused by immune-mediated mechanisms is detected. Thrombocytopenia, mild leukocytosis, or leukopenia are inconsistent findings. However, lymphopenia is frequently reported in dogs with VL. Test results for antinuclear antibodies can be positive in dogs with *L. infantum* infections, especially if co-pathogenic infections are present.¹⁹⁵ Parasites are rarely detected in peripheral blood.^{71b}

Definitive diagnosis of leishmaniasis can be confirmed by microscopic demonstration of parasites in cytologic preparations or histopathologic specimens, serology, culture of the organism in appropriate medium, or detection of parasite DNA using molecular methods.

73.1.5.2 Serologic Testing

Various serologic methods have been used to detect serum anti-*Leishmania* antibodies. Methods have included indirect fluorescent antibody testing, the enzyme-linked immunosorbent assay (ELISA), direct agglutination assays, and Western blotting.^{*} A purified recombinant antigen for ELISA, rK39, has been used for detection of VL in people and dogs.^{176,182,152a} In general, these methods have good sensitivities and specificities for the diagnosis of clinical VL. In naturally infected dogs, antibodies are present usually long before clinical signs of disease appear. Asymptomatically infected dogs that are slowly developing overt disease are often seropositive. However, a low positive titer result may be detected in animals that have been exposed but have not developed disease or in dogs that are persistent asymptomatic carriers. In an animal with compatible disease signs, a positive titer result strongly supports the preliminary diagnosis. Antibodies are very rarely undetectable in dogs with clinical signs of leishmaniasis. However, serology is thought to underestimate the true prevalence of asymptomatic infection in canine populations in endemic regions.^{118,199} In cases with inconclusive serologic results, additional detection methods are advised.¹⁰⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

Decreasing titer results have been used to monitor therapy,^{13,66,213} but titer results may decrease with the reduction in parasitic burden and not necessarily with total parasite elimination. Therefore results are often not consistent with parasitic cure, and relapses can occur frequently despite an initial lowering in antibody titer results. Serologic cross-reactivity with other pathogens is a problem in regions where *Trypanosoma* spp. are found, particularly in South and North America, where *Trypanosoma cruzi* is a pathogen of domestic canines and wild carnivores.⁹⁰

* References 71, 94, 126, 152, 184, 211, 214.

73.1.5.3 Organism Identification by Microscopy and Culture

Definitive diagnosis is usually based on cytologic or histologic identification of amastigotes—either contained in macrophages or free—in routinely stained smears from lymph nodes, splenic aspirates, skin touch impressions, or bone marrow. The specificity of these methods is virtually 100%, but depending on the time spent searching for parasites, the maximum sensitivity is $\pm 80\%$ in dogs with clinical signs of the disease and lower in asymptomatic seropositive dogs. Cytologic studies may reveal few or no demonstrable parasites in dogs with overt clinical signs of disease. Identification of amastigotes in formalin-fixed, paraffin-embedded sections of canine skin or visceral tissues may be facilitated by immunohistochemical methods such as immunoperoxidase staining.^{33,68} The diagnosis may also be established by the culture of parasites from tissues in Novy-MacNeal-Nicolle medium or Schneider's *Drosophila* medium or by the inoculation of hamsters.

73.1.5.4 Polymerase Chain Reaction

PCR demonstration of leishmanial DNA in tissues of infected animals is sensitive. It is routinely used for diagnostic purposes, epidemiologic studies, and screening for human and canine blood donors.^{13,134} Several protocols with different target gene sequences have been used in laboratories. The small-subunit rRNA gene, the internal transcribed spacer of the ribosomal operon, and high-copy sequences of kinetoplast DNA (kDNA) are frequently used as PCR targets.¹¹³ PCR can be performed on DNA extracted from tissues, blood, or even histopathologic specimens.^{99,178} Noninvasive conjunctival PCR has recently been shown to be accurate in the direct diagnosis of canine infection.²⁰²

73.1.6 Pathologic Findings

Severely affected patients with chronic symptomatic disease are usually cachectic. The organs primarily affected are the skin and hemolymphatic organs. Generalized enlargement of lymph nodes and splenomegaly are usually present. Hepatomegaly may be present but is less common. Small, light-colored focal nodular granulomas may develop in various organs, including the skin and the kidneys. Mucosal ulcerations in the stomach, intestine, and colon are occasionally observed. Petechiae and ecchymotic bleeding in mucosal and serosal membranes develop in some cases. Osteolytic or proliferative periosteal lesions may be found in various parts of the skeleton.⁵

Histopathology reveals granulomatous perifolliculitis and perivascular dermatitis. Multifocal or diffuse plasmacytic infiltration of the skin, spleen, lymph nodes, liver, kidneys, bone marrow, intestine, and conjunctiva may be observed, with an occasional or large numbers of amastigotes in macrophages. Renal

Infectious Diseases of the Dog and Cat, 3rd Edition

lesions include glomerulonephritis, interstitial nephritis, and occasionally amyloidosis.^{147,222} Amyloidosis may also be present in the liver and other organs. Nervous system involvement with *Leishmania* organisms in choroid plexus inflammatory cells has been reported.¹⁴⁹

73.1.7 Therapy

73.1.7.1 Dogs

Canine leishmaniasis in dogs is more resistant to therapy than human leishmaniasis, and only rarely are *Leishmania* organisms completely eliminated with available drugs.¹⁹ Relapses necessitating retreatment are the rule rather than the exception, although some dogs may eventually become cured of the clinical disease (Table 73-4).

For decades, pentavalent antimonials (Sb^{5+}) have been the primary drug for treatment of canine and human VL. They selectively inhibit the protozoal enzymes required for glycolytic and fatty acid oxidation. Two Sb^{5+} -containing agents have been administered to dogs: meglumine antimoniate (trade name Glucantime; Merial, Lyon, France) and sodium stibogluconate (trade name Pentostam; Wellcome Foundation Ltd, United Kingdom; see Drug Formulary, Appendix 8). Both agents must be injected daily and may cause serious adverse effects. Meglumine antimoniate appears to cause milder side effects, but it is not licensed for use in some countries, including the United States. Sodium stibogluconate is currently involved in an investigational new drug protocol for human physicians through the Centers for Disease Control and Prevention (CDC) in the United States. The development of *L. infantum* strains that are resistant to Sb^{5+} has been reported in France, Spain, and Italy and is a major veterinary and public health concern.^{37,38,86,116}

Dosage regimens for Sb^{5+} vary widely. Sb^{5+} is quickly excreted in the urine. Only a small part is reduced to the toxic Sb^{3+} , which may accumulate in the body. However, normal doses of the drug rarely cause signs of toxicity unless administered daily for longer than 2 months or administered to a patient with renal, cardiac, or hepatic failure. Antimonials may be injected intramuscularly (IM), subcutaneously (SC), or intravenously (IV). IM injections in the thigh have resulted in severe lameness as a result of muscle fibrosis. Possible local complications of SC administration are less serious but include local inflammation. IV injections may cause thrombophlebitis and hence thrombosis. Results of pharmacokinetic studies of Sb^{5+} compounds in dogs are controversial,^{205,209} but the clinical effect and parasitologic clearance is the same when 100 mg/kg of meglumine antimoniate is given IV once daily or SC divided into two daily doses.¹⁹³

Table 73-4 Antimicrobial Therapy for Canine Leishmaniasis

DRUG ^a	DOSE (MG/KG) ^b	ROUTE	INTERVAL (HOURS)	DURATION ^c (WEEKS)
Meglumine antimoniate (Glucantime)	100	IV, SC	24	3–4
Sodium stibogluconate ^d (Pentostam)	30–50	IV, SC	24	3–4
Allopurinol ^e	20	PO	12–24	Indefinitely

IV, Intravenous; SC, subcutaneous; PO, by mouth.

Infectious Diseases of the Dog and Cat, 3rd Edition

- a For additional information on use of these drugs, see Drug Formulary, [Appendix 8](#).
- b Dose per administration at specified interval.
- c All long-term survivors must be treated on multiple occasions because of relapses.
- d Available in the United States for treatment of human infections by special request from the Centers for Disease Control and Prevention, Atlanta, Ga.
- e Some studies suggest that combined therapy with allopurinol and antimony compounds is the most effective for treating *L. infantum* infections.

An alternative to Sb^{5+} injection in dogs is therapy with allopurinol^{39,110} (see Drug Formulary, [Appendix 8](#)). Allopurinol is a hypoxanthine compound that is metabolized by *Leishmania* spp. to produce an analogue of inosine. The analogue is incorporated into leishmanial RNA, causing faulty protein translation and inhibition of parasite multiplication. This drug is less expensive than Sb^{5+} compounds, can be administered orally, has few adverse effects, and is readily available, even in the United States and other countries. Use of allopurinol causes hyperxanthinuria, which may incidentally produce urolithiasis. It is used with increasing frequency by veterinarians, often in combination with Sb^{5+} .^{8,52,66,82,207} Dosage schedules vary widely, and the optimal dose has not been defined. Clinical remission is frequently obtained by treating with allopurinol alone. A dose of 20 mg/kg once daily often results in remarkable clinical improvement within 4 weeks and reduction of parasites to undetectable numbers. However, relapses consistently occur once therapy has been discontinued. Even after conscientious administration of the drug for 6 months, complete recovery is rare.¹¹⁹ Relapses develop more insidiously and are often less serious than with meglumine; however, deterioration of kidney function may commence during allopurinol therapy despite resolution of dermal lesions and general improvement in the clinical condition. This progression is likely caused by continuation of immune complex deposition. When Sb^{5+} is used as the initial drug for treatment, allopurinol may be used in combination.^{158b} At the end of combined treatment, allopurinol is commonly recommended for long-term maintenance therapy or even indefinitely for dogs diagnosed with symptomatic leishmaniasis. In a study from Holland, dogs treated with 20 mg/kg per day of allopurinol had a 78% chance of survival for more than 4 years (if they did not have severe renal failure when therapy was started).¹⁹⁴

Amphotericin B (AMB), a polyene macrolide primarily used as an antifungal drug, also has activity against some protozoa. It acts by binding to ergosterol and altering the cell membrane permeability. AMB has a profound toxic effect on the canine kidney by causing renal vasoconstriction and reduction of the glomerular filtration rate and possibly by acting directly on renal epithelial cells. It can be administered to dogs with leishmaniasis in a highly nephrotoxic free form, lipid emulsion, or liposomal formulation that reduces its toxic effects and directs the drug to being taken up by macrophages and accumulating in visceral organs. Liposomal AMB is effective in the treatment of people and has largely replaced therapy of human patients with antimonials in Italy and other European countries.⁸⁶ However, a study on the use of liposomal AMB in dogs failed to show that treated dogs had long-term clinical improvements with elimination of the infection.¹⁵⁰ The use of AMB in a lipid emulsion of soybean oil administered IV to dogs pretreated with saline and mannitol has had higher clinical cure success rates and more negative posttreatment parasitologic tests in some animals. This therapy is associated primarily with transient side effects of anorexia and vomiting and requires careful monitoring of renal parameters.^{42,115}

Additional drugs that are not recommended as first-line therapy for canine VL because of the adverse effects associated with treatment include pentamidine and aminosidine.^{166,175} Pentamidine, an aromatic diamidine used also for pneumocystosis, babesiosis, and trypanomiasis, is injected IM in dogs and can cause severe

Infectious Diseases of the Dog and Cat, 3rd Edition

irritation at the site of injection, hypotension, tachycardia, and vomiting. Aminosidine sulphate is an aminoglycoside antibiotic that is toxic at doses that are clinically effective against *Leishmania*. Other drugs that are being investigated for the treatment of canine leishmaniasis include alkylphosphocholine derivatives related to the drug miltefosine, which is used for treating some forms of human VL,^{199a} and metronidazole.

In a trial comparing the efficacy of conventional treatment with meglumine antimoniate and allopurinol against use of metronidazole and spiramycin, treated dogs showed some clinical improvement without a parasitologic cure, similar to control dogs.^{160a}

If dogs are seriously ill, and especially if they are in severe renal failure, it may be necessary to restore fluid and acid-base balances before antileishmanial drugs are administered. Because of its lower toxicity, allopurinol is preferred to a Sb^{5+} compound in these cases. The prognosis of canine leishmaniasis depends on the severity of injury to the dog's systems at the time of diagnosis and the dog's individual response and rate of deterioration. In dogs that have not reached a progressive state of renal failure, treatment frequently significantly improves dermal and visceral signs of the disease. Immune responses were monitored in dogs before and after treatment and have indicated that in some cases, parasite-specific cell mediated immunity that is absent before therapy is regained after drug administration but may deteriorate again during a clinical relapse.^{53,143,175}

694

73.1.7.2

Cats

695

Almost no published information is available on drug therapy for feline leishmaniasis. One cat in Spain with primarily cutaneous lesions was treated with 5 mg/kg of meglumine antimoniate SC combined with 10 mg/kg ketoconazole orally. A 4-week course of combined therapy was repeated three times, with 10 days without therapy between each course, and resulted in the resolution of the cutaneous lesions.⁹⁶ Topical treatment of cutaneous *L. mexicana* infection in a cat with clotrimazole and subsequently with paromomycin did not improve the dermal lesions.²⁰

73.1.8

Control and Prevention

Efforts to control leishmaniasis in the canine populations in endemic countries are controversial and generally have not been considered to be successful.^{14,44,59,158} Killing symptomatic and seropositive dogs is obviously unacceptable to the owners, but it is also ineffective because nonsymptomatic dogs, occasionally seronegative dogs, and possibly wild canids are sources of parasite transmission. Furthermore, available methods for testing do not identify all infected dogs, and a population of young susceptible puppies can replace the culled animals.¹⁴⁵ Spraying for sandfly vectors and eradicating their presumptive breeding places has limited effectiveness in preventing spread of the disease. No prophylactic drug has yet been shown to be effective against infection, and medical treatment of infected dogs with antileishmanial drugs is ineffective in eliminating the parasite.

Sandfly vectors of VL are primarily active outside houses, therefore selective spraying inside houses is ineffective. However, spraying inside and around kennels could reduce the risk of infection. Measures to protect the individual dog include keeping the animal indoors as much as possible from 1 hour before sunset to 1 hour after dawn during the vector season and installation of fine-mesh screens to keep sandflies out of kennels. Topical insecticides for protecting dogs against sandfly bites include solutions, spot-on tubes, sprays, and collars. A spray containing permethrin and pyreproxylene (trade name Duowin; Virbac, Fort Worth, Tex.,

Infectious Diseases of the Dog and Cat, 3rd Edition

www.virbacorp.com) is recommended every 3 weeks for adult dogs and every 2 weeks for puppies.¹³⁹ A spot-on containing imidacloprid and permethrin (K9 Advantix,® Bayer, Leverkusen, Germany) is recommended for dogs every 4 weeks for repelling sandflies. Deltamethrin-impregnated collars (trade name Scalibor; Intervet, Boxmeer, Netherlands; www.intervet.com) have been shown to protect dogs for about 8 months from more than 90% of bites from *Phlebotomus perniciosus*, the primary vector of *L. infantum* in France, and *Lutzomyia longipalpis*, a major South American vector.^{50,106} A controlled study on the effect of using collars on dogs in a focus of VL in Iran indicated that the seroconversion rate after 1 year in dogs and children in intervention villages was significantly lower than in control villages.¹³⁶ Topical insecticide protection appears to be valuable for dogs in endemic regions during transmission seasons and for dogs traveling to these areas. Use of collars on client-owned infected dogs treated medically and living in infected areas is warranted.

Vaccination of dogs against VL could be a major preventative measure. Trials with several types of candidate vaccines for *Leishmania* in animal models have been carried out during the past 4 decades. These included the assessment of attenuated or killed whole parasites, purified parasite fractions, recombinant antigens, live bacteria expressing *Leishmania* antigens, DNA vaccines, and the use of numerous adjuvants.^{31,31a,85} A canine vaccine is now commercially available in Brazil, and another vaccine brand is likely to be marketed in Europe in the near future.

73.1.9 Public Health Considerations

VL is a serious human disease that may be fatal if untreated. Malnutrition appears to be a predisposing factor for the progression of infection.^{11,17} Traditionally, VL primarily affected young children and infants, but now it is also often a complication in adults infected with HIV or those receiving cytostatic or immunosuppressive drugs.^{88,101,177,218}

Transmission of *L. infantum* from dogs or wild canids to people via sandflies is considered to be the primary route of infection involved in zoonotic VL. Asymptomatically infected dogs have been shown to be infectious to sandflies, and symptomatic dogs may be infectious shortly after treatment with antileishmanial drugs.⁸ Ownership of an infected dog does not appear to be a major risk factor for human infections in Europe, where the ratio of clinically affected people to dogs is usually low. However, a study from Iran indicated that dog ownership is a significant risk factor for childhood seropositivity.¹³⁷ The link between dog and human infections probably differs from one region and life style to another and could depend on multiple factors including human nutrition, time spent outdoors, the density of dogs, and the behavior of sandfly vectors. Transmission by direct contact between dogs and people is speculated to be rare, if it occurs at all, and although it has not been well documented, it cannot be ruled out. Transmission of *L. infantum* through blood products has been reported in dogs that received blood transfusions from infected canine donors and in people.¹⁵³ Studies in Spain of humans who use IV drugs and share needles have indicated that the infection was transmitted through the needles.⁴⁸ Therefore direct contact with contaminated hypodermic needles or with open wounds or exudates from dogs with leishmaniasis should be avoided.

Infected pets may remain disease carriers despite treatment. In areas where sandfly vectors are found, this poses a problem to owners, veterinarians, and local public health and environmental agencies who are concerned with the risk to people and animals. Before deciding on the fate of an infected pet, owners should be consulted and educated about the disease, its zoonotic nature, the prognosis for their dog, what should be expected from

Infectious Diseases of the Dog and Cat, 3rd Edition

therapy, and safety precautions that should be taken. A clear, official policy based on relevant research and a calculated estimation of the risk to the community is desirable.

73.2 CANINE AND FELINE AMERICAN TEGUMENTARY LEISHMANIASIS

Gad Baneth

Cutaneous (tegumentary) leishmaniasis is caused by *L. (V.) braziliensis*, *L. (V.) peruviana*, or related species and affects dogs and people in South America. Infection in dogs has been reported from Brazil, Argentina, Bolivia, Peru, Ecuador, Colombia, Venezuela, and Panama.^{123,173} Sporadic infection of cats has also been reported.^{159,186,59a,200a} Outbreaks of American tegumentary leishmaniasis have been associated with deforestation of jungle areas.¹⁵⁵

The clinical signs of disease in dogs include chronic ulcerative lesions on the ears or other areas of the skin, mucocutaneous erosive lesions, and lymphadenomegaly.^{129,155,164} Ulceration sometimes involves the nasal or auricular cartilage.¹²⁹ Hematogenous dissemination of parasites in dogs is likely, and the presence of parasite DNA has been demonstrated by PCR of the blood and bone marrow from symptomatically and asymptotically infected dogs.¹⁷⁴ Cats have developed cutaneous nodular lesions on their skin. Diagnosis can be confirmed by microscopic detection of parasites in lesions, in culture, by specific serologic tests, or by PCR. The number of parasites found in canine dermal lesions is usually low. Infected dogs respond to antimonial therapy; however, they remain infected after therapy and commonly have clinical relapses.¹⁶⁴ Numerous wild animals including opossums and rodents have been reported to be infected with the agents of tegumentary leishmaniasis. Although it is involved in this disease, the dog does not appear to be a significant reservoir host of infection for people.¹⁷³

695

696

73.3 CANINE VISCERAL LEISHMANIASIS IN NORTH AMERICA

Edward B. Breitschwerdt

Peter Schantz

Endemic VL is an emerging disease in dogs in North America. Although human and canine VL are well established in parts of Asia, Africa, southern Europe, Central America, and South America, VL has been infrequently reported in people and domestic animals in the United States and Canada.

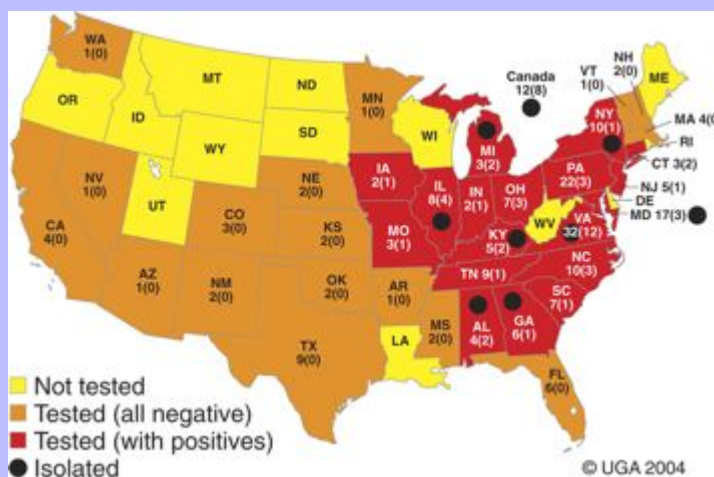

73.3.1 Etiology

Before 2000, most cases of canine VL in the United States and Canada were associated with a history of international travel.^{98,119,183,219} However, between 1980 and 2001, four reports of canine VL were made in which the dogs had no history of foreign travel. These reports included an American foxhound from a kennel in Oklahoma, an English foxhound maintained in a closed research colony at The Ohio State University, a pet basenji from Texas, and a pet toy poodle from Maryland.^{9,62,189,204} The infected dogs in these reports had not traveled outside of the United States, and neither a source of infection nor an insect vector was ever identified. Two additional outbreaks of VL in foxhounds were recognized by one of the authors in kennels in Michigan in 1989 and Alabama in 1994. Since that time, several laboratories have identified serologic, molecular, or culture-based evidence of *L. infantum* infection in numerous foxhounds that are indigenous to the United States (Fig. 73-12).⁶⁰ Retrospectively, it now appears that canine VL was established as an autochthonous disease in

Infectious Diseases of the Dog and Cat, 3rd Edition

American foxhounds in North America, at least after 1979.⁹ Investigation of a disease outbreak among foxhounds in an index kennel located in Dutchess County, New York, ultimately led to the discovery that infection with *L. infantum* was well established in foxhounds throughout much of North America. The initial outbreak investigation involved a cooperative effort among the College of Veterinary Medicine at North Carolina State University, the Division of Parasitic Diseases in the National Center for Infectious Diseases of the CDC (Atlanta, Ga.), the Walter Reed Army Institute of Research (Washington, DC), the New York State Department of Agriculture and Markets and Department of Health, local veterinarians, and the kennel owners and staff.⁸¹ At the time VL was diagnosed in the four index cases, 46 (41%) of 112 dogs in the New York foxhound kennel were infected. Infection was diagnosed by a positive *Leishmania* culture result, PCR amplification of *Leishmania* DNA, identification of amastigotes by cytology or histopathology, or seroreactivity (all titers equal to or greater than 1:64) to *Leishmania* antigens. This suggested a high rate of exposure or infection with *Leishmania* species within the kennel population, particularly because serologic testing tends to underestimate the prevalence and incidence of *Leishmania* infections in endemic regions. After infection, dogs or people can remain subclinically infected for months to years before the onset of disease manifestations.

Fig 73-12 Seroprevalence of leishmaniasis in dog kennels. Numbers tested are shown, and number with positive results are in parentheses. Solid dots indicate states where organism has been isolated from affected dogs. (Data courtesy Zandra Duprey, Centers for Disease Control and Prevention, Atlanta, Ga.; map courtesy, University of Georgia, Athens, Ga.)

Subsequent to the New York kennel investigation, the CDC screened more than 10,000 foxhounds and found seropositive foxhounds in 69 kennels in 21 states and 2 Canadian provinces.¹⁸⁵ Now that this disease has become endemic in the United States, it is possible that leishmaniasis will be recognized more often in dog breeds other than American foxhounds. In addition, autochthonous human cases may be diagnosed in the United States in the future.

Infectious Diseases of the Dog and Cat, 3rd Edition

73.3.2 Epidemiology

In endemic regions, Phlebotomine sandflies (genus *Lutzomyia* in the New World) are the primary insect vectors for transmission of *Leishmania* spp.^{70,173} In addition to dogs and humans, cats, horses, coyotes, foxes, and rodents can be infected with *Leishmania* spp. However, dogs are considered the primary *L. infantum* reservoir in endemic countries in southern Europe (France, Italy, Spain, and Malta). Based on isoenzyme electrophoresis, many of the North American isolates obtained from 40 foxhounds, including the isolate obtained from a foxhound in Oklahoma in 1980, are *L. infantum* MON-1, which is the predominant *Leishmania* zymodeme found in southern Europe.^{9,81,89} In endemic regions the protozoal life cycle begins when the infective form—the promastigote—is injected into the skin of the vertebrate host by the sandfly (see Fig. 73-4).¹⁰⁴ After entering the host, the promastigote is transformed into the nonflagellated form—the amastigote. Amastigote multiplication in macrophages occurs by binary fission either locally in the cutaneous or mucocutaneous forms or systemically throughout the reticuloendothelial system in the visceral form. Vectors ingest amastigotes while obtaining a blood meal from the infected host. If ingested by an unsuitable vector, the amastigotes are either destroyed or passed out in the feces. If the vector is suitable, ingested amastigotes transform into promastigotes and attach to the midgut epithelium of the sandfly. Promastigotes then detach and move cranially to the foregut, where some attach and others remain free for subsequent transmission through a bite, which completes the transmission cycle. In certain regions, additional epidemiologic complexity is created by the ability of certain sandflies to serve as hosts to multiple *Leishmania* spp.

Fourteen species of *Lutzomyia* sandflies have been recorded in North America, and only three (*Lutzomyia shannoni*, *Lutzomyia diabolica*, and *Lutzomyia vexator*) have been suspected as vectors for *Leishmania* spp.^{104,117,220} Because of the lack of human leishmaniasis in the United States, protozoal research laboratories have only recently evaluated indigenous sandfly species for their ability to transmit *L. donovani*. The most prevalent sandfly in the southeastern United States (all Atlantic coastal states south of Pennsylvania and west to Louisiana) is *L. shannoni*. Previous studies have demonstrated that *L. shannoni* develop a very heavy parasitemia when feeding on dogs infected with *L. infantum*; however, the vector competence of *L. shannoni* for transmission of *L. infantum* has not been established. In the previously mentioned New York kennel, a significant correlation was found between a positive *Leishmania* status and *Ehrlichia canis* seroreactivity ($p=0.03$).⁸¹ Although not thought to occur in nature, *L. infantum* has been experimentally transmitted by *Rhipicephalus sanguineus*, a known vector for *E. canis*.¹³⁸ Foxhounds with a positive *Leishmania* status were 5 times more likely to have traveled to the southeastern United States or to have been older than 18 months of age. These factors tend to support the presence of a competent insect vector, potentially in the southeastern United States. No evidence supports vector transmission in the northeastern United States; adjacent foxhound kennels and beagles and basset hounds housed on the same premises during the summer months had no serologic evidence of exposure to *L. infantum*.⁸¹ Serologic screening of pet dogs, coyotes, and foxes from the United States has not resulted in the detection of *L. infantum* antibodies.⁸¹ The mode of *L. infantum* transmission among foxhounds in North America has not yet been determined.

Foxhound kennels are geographically distributed throughout much of the United States. Because of the substantial number of foxhounds with serologic evidence of exposure to *Leishmania* species, dog-to-dog transmission via direct contact, exposure to blood products from an infected dog, or possibly during parturition or breeding may explain the high prevalence of leishmaniasis in this breed. Historic evidence from nonendemic countries supports dog-to-dog transmission by direct contact (referred to as *mechanical transfer*) and perinatal transmission.^{127,194} Leishmaniasis can also be transmitted from dog to dog by blood transfusions.¹⁵³ In these

Infectious Diseases of the Dog and Cat, 3rd Edition

instances, macrophages containing amastigotes serve as the source of infection. The Penn Animal Blood Bank at the Veterinary Hospital of the University of Pennsylvania has documented transmission of *L. infantum* from foxhound donors to canine patients.¹⁵³ Because of the high *L. infantum* seroprevalence, the use of foxhounds as blood donors in North America may not be advisable, particularly because serologic testing may not detect chronically infected dogs.

73.3.3 Clinical Findings

Clinical manifestations in foxhounds included chronic wasting, conjunctivitis, anterior uveitis, retinitis, facial alopecia, severe muscle atrophy, lymphadenopathy, polyarthritis, and protein-losing nephropathy, which may be accompanied by renal failure.^{81,153} These are the same abnormalities associated with canine VL in endemic regions. Despite chronic infection, hematologic and biochemical abnormalities may be mild or absent. When present, anemia, thrombocytopenia, lymphocytosis, hypoalbuminemia, hyperglobulinemia, hyperamylasemia, and azotemia are the most frequently detected laboratory abnormalities. In addition to foxhounds, other breeds of dogs with unexplained wasting disease, especially if accompanied by hypergammaglobulinemia, bilateral facial alopecia similar to the pattern observed for demodectic mange, or unexplained glomerulonephritis and protein-losing glomerulonephropathy, should be tested for exposure to *L. infantum*. In pet dogs, owners have reported behavioral changes, including an increase in aggressive tendencies, as the first indication of leishmaniasis.

73.3.4 Diagnosis

VL can be diagnosed by cytologic or histopathologic identification of organisms, isolation of amastigotes, detection of serum antibodies, or PCR amplification of leishmanial DNA. Antibody titers of greater than 1:16 are considered indicative of *Leishmania* exposure.¹⁸⁵ However, serologic cross-reactivity between *Leishmania* spp. and *T. cruzi* can occur, a factor that should be considered, particularly in kennel or hunting dogs. Although *T. cruzi* is enzootic among wild animals throughout much of North America, reports of infections in domestic dogs have generally been limited to Texas, Louisiana Oklahoma, and Virginia (see [Chapter 72](#)).^{21,22,79} The extent to which infection with *T. cruzi* contributes to the high level of seroreactivity to *Leishmania* species antigens in North American foxhounds remains unclear. Western immunoblotting or the use of a *T. cruzi*-specific ELISA test (developed for humans) may help differentiate between exposure to *L. infantum* and to *T. cruzi*. Although presumably infrequent, dogs can be infected with *Leishmania* species without developing a detectable antibody response. In foxhounds, this is particularly true when a dog is chronically infected but has not developed clinical disease manifestations. As an alternative to serologic testing, PCR can be used to confirm the diagnosis. Of the seroreactive foxhounds from the New York kennel, infection in 65% (26 out of 40) was confirmed by PCR detection of *Leishmania* species DNA in peripheral blood anticoagulated by ethylenediaminetetraacetic acid (EDTA).⁸¹ Peripheral blood was selected as the diagnostic sample for PCR because of convenience; however, the sensitivity of PCR to confirm *Leishmania* infection in seropositive dogs or to detect subclinical infection can be enhanced by examination of lymph node or bone marrow aspirates rather than blood.^{13,171} For diagnostic assistance with leishmaniasis, serum (for antibody determination) or EDTA blood (for PCR) samples can be submitted to the Vector-Borne Diseases Diagnostic Laboratory, North Carolina State University, Raleigh, N.C. (Contact the laboratory for appropriate submission forms before submitting specimens; see [Appendix 5](#) for specific contact information for this laboratory.)

Infectious Diseases of the Dog and Cat, 3rd Edition

73.3.5 Therapy

For details regarding treatment of sick dogs, refer to the previous general *Leishmaniasis* section in this chapter. No treatment protocol has been proved to cure VL in dogs.⁶⁵ Despite clinical improvement or a clinical cure (i.e., a healthy appearance after treatment), relapses are common, and chemotherapeutic elimination of *L. infantum* has not been achieved with any drug tested. However, continuous chemotherapy with allopurinol most likely decreases the parasitemia to a level that has little risk of direct or sandfly transmission (see [Table 73-4](#)).^{39,52} Therefore this approach could be used for the medical management of pet or kennel dogs in the United States; however, periodic (every 6 months to 1 year) serologic screening of uninfected dogs in the kennel or household is recommended. In nonendemic regions, euthanasia has been promoted to prevent leishmaniasis from becoming established. Some foxhound kennels have adopted a test-and-elimination approach in an effort to remove infected dogs from the environment.

73.3.6 Public Health Considerations

Because of sandfly exposure in endemic regions, the incidence of leishmaniasis in people is about 2 million cases per year (1.5 million cases of the cutaneous form and 500,000 cases of the visceral form).²¹⁷ If untreated, leishmaniasis is generally fatal. Disease manifestations in people can be quite nonspecific in immunocompetent individuals; however, children and severely immunocompromised people are most likely to develop serious disease manifestations. *L. infantum* was detected by PCR and culture in asymptomatic carriers who were blood donors in France.⁶⁷

Numerous pet dogs belonging to military personnel and other individuals from *Leishmania*-endemic regions are being transported to the United States.¹⁵¹ Although potentially chronically infected, these dogs can remain healthy for months to years after being introduced or reintroduced to United States. If sandflies in North America are able to transmit VL from infected to susceptible dogs, then vector transmission of this serious human pathogen from infected dogs to humans is possible. An autochthonous human case of VL from the United States has not been reported, and no data supports vector transmission among dogs in North America.

Infectious Diseases of the Dog and Cat, 3rd Edition

74 CHAPTER 74 Hepatozoonosis

Hepatozoonosis is an arthropod-borne infection caused by apicomplexan protozoa from the family Hepatozoidae in the suborder Adeleorina.¹⁶ Based on analysis of 18S ribosomal DNA sequences and morphologic features, parasites in the genus *Hepatozoon* are believed to be most closely related to other apicomplexan parasites such as *Plasmodium* spp. and piroplasms.¹⁷ More than 300 different species of *Hepatozoon* have been described in amphibians, reptiles, birds, marsupials, and mammals.⁹⁴ Of these, more than 120 species infect snakes, and approximately 50 have been reported in mammals. The genus was named *Hepatozoon* because merogonic development of the type strain *Hepatozoon muris* was observed in the liver of rats.⁶⁸ However, the liver is not necessarily a major target tissue for other *Hepatozoon* spp. *Hepatozoon* spp. that infect amphibians, reptiles, and avian hosts parasitize mainly erythrocytes, whereas gamonts of *Hepatozoon* spp. infecting mammals are found primarily in leukocytes. *Hepatozoon* spp. have a basic life cycle that includes asexual development with merogony followed by gamontogony in a vertebrate intermediate host such as the dog and sexual development leading to sporogony in a hematophagous invertebrate definitive host such as a tick. A variety of blood-sucking arthropod vectors serves as definitive hosts for different *Hepatozoon* spp. These hosts include ticks, mites, mosquitoes, sand flies, tsetse flies, fleas, lice, and reduviid bugs.⁹⁴ Unlike many vector-borne protozoal and bacterial pathogens that are transmitted via the salivary glands, *Hepatozoon* transmission takes place by ingestion of the definitive host, an invertebrate that contains mature oocysts, by the intermediate vertebrate host. Two species that use domestic dogs as the intermediate host, *Hepatozoon canis* and *Hepatozoon americanum*, have been identified. Infections caused by *H. canis* and *H. americanum* will be discussed in two separate sections in this chapter.

74.1 HEPATOZOON CANIS INFECTION

Gad Baneth

74.1.1 Etiology

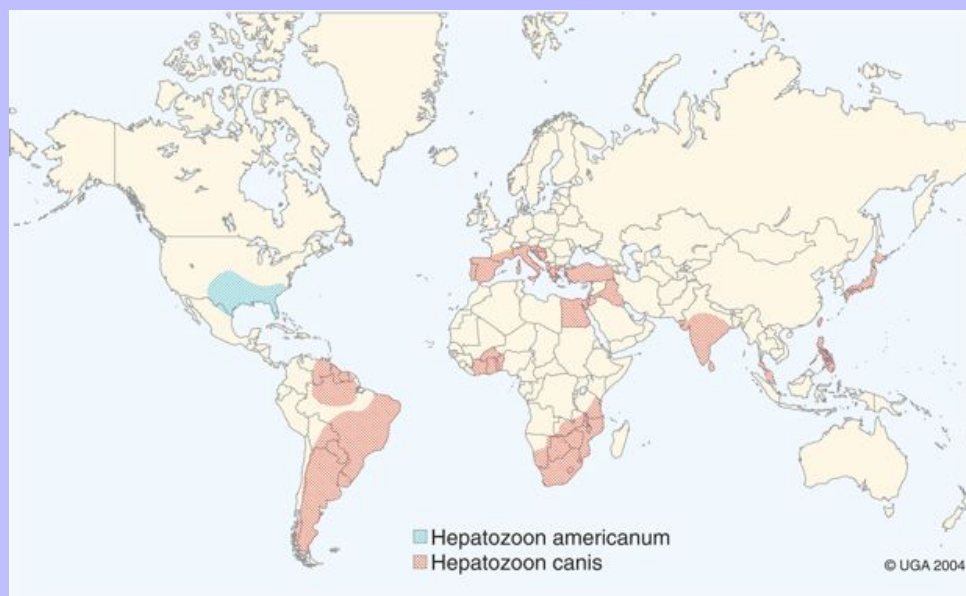

74.1.1.1 Dogs

H. canis infection (HCI) in dogs was first described from India in 1905,⁴⁸ and until 1997, the presumption was that canine hepatozoonosis was caused by a single species. However, research elucidating the pathologic and clinical syndromes associated with hepatozoonosis,^{*} its transmission by tick species, the parasite life cycle,^{9,63,64} and genetic and antigenic characterization of *Hepatozoon* isolates,^{4,66} has led to the recognition that two distinct *Hepatozoon* spp. infect dogs. This finding resulted in naming the parasite that infects dogs in the southern United States *H. americanum*¹⁰⁰ and separating it from the previously described *H. canis*.⁸ The discussion in this first section will focus on *H. canis* infection.

74.1.1.2

Cats and Wild Carnivores

The host range of *H. canis* in mammalian carnivores other than the domestic dog has not been clarified. *H. canis* or *Hepatozoon* spp. morphologically resembling *H. canis* have been reported from several wild canine species, from domestic and wild felines, and from other carnivore species, including the red fox (*Vulpes vulpes*),^{21,24,62} crab-eating fox (*Ceronyx thous*),¹ black-backed jackal (*Canis mesomelas*),⁶⁷ golden jackal (*Canis aureus*),⁹² African wild dog (*Lycaon pictus*),⁹⁶ hyena (*Crocuta crocuta*),⁶⁷ palm civet (*Paradoxurus hermaphroditus*),⁵⁵ cheetah (*Acinonyx jubatus*),⁶⁷ leopard (*Panthera pardus*),⁶⁷ lion (*Panthera leo*),²⁸ and Pallas cat (*Felis manul*).¹⁵ Although the probability that *H. canis* may infect other animals species is high, particularly those that are closely related to the domestic dog, this has not been demonstrated by experimental transmission or genetic characterization and comparison of isolates. Reports before 1997 of *H. canis*-like organisms in North American wild carnivores are possibly related to the species known today as *H. americanum* or to a species other than *H. canis*. For a further discussion on feline hepatozoonosis, see the following section.

Infectious Diseases of the Dog and Cat, 3rd Edition

74.1.2 Epidemiology

74.1.2.1 Geographic Distribution and Prevalence

HCI is prevalent in regions of tropical, subtropical, and temperate climate. HCI has been reported from the domestic dog (*Canis familiaris*) from most continents and numerous countries, including Greece,⁵⁴ Italy,³⁹ France,⁸⁹ Spain⁴⁹ and Portugal in southern Europe; Israel⁵⁰ and Egypt³⁶ in the Middle East; South Africa⁶⁷ and Nigeria³⁵ in Africa; India,⁴⁸ Sri Lanka, Singapore,⁵⁵ Malaysia,⁸⁸ The Philippines,⁷⁷ Thailand,⁹⁰ and Japan⁷⁵ in Asia; and Brazil,⁴⁰ Argentina, and Venezuela in South America (Fig. 74-1). In addition, imported cases of HCI in dogs brought into nonendemic areas have been detected in several countries, including Germany and Holland.^{25,37} The homogeneity of different *H. canis* isolates using comparison of conserved DNA sequences has not been studied thoroughly. However, a phylogenetic analysis of a partial sequence of the 18S ribosomal RNA gene from *Hepatozoon* isolates from dogs in Japan indicated that these isolates had a 99% identity with *H. canis* sequenced from Israel and were more distant to *H. americanum*.⁴⁷

The prevalence of HCI in different regions ranges considerably. Circulating *H. canis* gamonts were detected in 39% of the dogs surveyed in rural areas of Rio de Janeiro state in Brazil,⁷⁸ in 22% of dogs surveyed in Zaria in Nigeria,³⁵ and in 1.2% in Malaysia.⁸⁸ Serologic studies of HCI revealed that 33% of the dogs surveyed in Israel¹² and 4.2% in the Yamaguchi region in Japan⁴⁶ had been exposed to the parasite, as indicated by the presence of anti-*H. canis* antibodies demonstrated by indirect fluorescent antibody (FA) testing. As found also for other tick-borne diseases, including canine ehrlichiosis, babesiosis, and Lyme disease, the exposure rate for HCI in endemic areas is often much greater than the prevalence of clinical disease. Most dogs that are infected with *H. canis* probably undergo a subclinical infection. Among the dogs surveyed for *H. canis* antibodies in Israel, of 33% seropositive dogs, 3% had detectable blood gamonts, and only 1% had severe clinical signs associated with the infection.¹²

74.1.2.2 Transmission

The distribution of canine hepatozoonosis is tied closely to its acarine definitive hosts. The primary vector of *H. canis* is the brown dog tick, *Rhipicephalus sanguineus*.^{9,20,103} It is a three-host tick that is considered to be the most widely distributed tick species in the world.¹⁰¹ *R. sanguineus* is adaptable to different environmental conditions and is found in warm and temperate regions, making the potential distribution of HCI widespread. *H. canis* is transmitted transtadially from the nymph to the adult stage in *R. sanguineus*. Possible transovarial transmission through the tick's ovary and eggs could not be demonstrated under experimental conditions.¹² *R. sanguineus* ticks can be infected experimentally through percutaneous injection of blood gamonts, allowing researchers to study the disease in ticks.⁹ Other tick species such as *Haemophysalis longicornus* and *Haemophysalis flava* are potential vectors and were reported to have been removed from dogs with HCI in Japan and identified with *Hepatozoon*-like oocysts in their hemocoel.⁷³

In addition to infection by ingesting ticks that contain mature oocysts, alternative modes of HCI transmission to dogs should be considered when studying the epidemiology of this disease. As for other apicomplexan parasites, including *Toxoplasma gondii* and *Neospora caninum* (Chapter 80), horizontal transmission through the uterus from dam to its offspring has also been demonstrated in HCI. Naturally infected pregnant bitches

Infectious Diseases of the Dog and Cat, 3rd Edition

were allowed to give birth in a tick-free environment. Meronts were found in the spleen of a pup that died 16 days after birth, and blood gamonts were detectable as early as 21 days in other pups.⁷² Another potential mode of transmission that has not been demonstrated in HCI is predation of one intermediate host on another intermediate or transport host. Experimentally, infection did not result from parenteral inoculation of tissues or blood from infected dogs but from inoculation of emulsified tick tissues.¹⁰⁴ Some species of *Hepatozoon* that infect snakes, lizards, and frogs are transmitted through predation and ingestion of tissue cysts found in intermediate host tissues.⁹⁴

74.1.2.3 Epidemiologic Characteristics

No gender or breed predilection for HCI has been noted. HCI was reported in all age groups, from pups younger than 3 months of age to old dogs.^{2,12,14} In a case series of dogs from Greece, the female-to-male ratio was 1.2:1, and the mean age was 4.2 years.⁵⁴ Dogs with HCI are more likely to be from a rural community as compared with an urban setting, which is probably the result of a higher exposure rate to ticks.¹⁴

Most HCI cases are detected during the warmer months of the year, when tick vectors are more abundant. In a case-control study of 100 dogs with HCI from Israel, 77% were admitted during the warm period of May through November.¹⁴ A follow-up study on the periodic appearance of *H. canis* gamonts in the blood of dogs in Japan indicated that the peak parasitemia was from spring to autumn.⁷⁴ However, HCI is also diagnosed during the colder months, when transmission by vector ticks is less likely, caused by chronic persistence of the infection.¹⁴

74.1.3 Pathogenesis

The presumption is that most dogs become infected with *H. canis* through grooming ticks from their haircoat or feeding on prey infested with parasitized ticks. *R. sanguineus* is a three-host tick that drops off its host when engorged with blood and, following molt, seeks another animal on which to feed. An adult tick stage might therefore acquire the HCI, as a nymph feeding on a parasitemic dog, and then after molting, attach and feed on a new host, not necessarily a dog. Experimental evidence has shown that both male and female adult *R. sanguineus* can harbor *Hepatozoon* oocysts and are potentially infective to dogs.⁹

The life cycle of *H. canis* involves the sequential formation of several distinct life forms in each of its two hosts, the dog serving as intermediate host and the tick as definitive host (Fig. 74-2). Some confusion has been caused by synonymous use of terms relating to life cycle stages of *H. canis*. Older literature often relates to schizonts and gametocytes, whereas current texts commonly use the terms meronts and gamonts, respectively. When the dog ingests the vector tick or tick parts, *H. canis* sporozoites release in the intestine and penetrate the gut wall. The sporozoites invade mononuclear cells and disseminate hematogenously or via the lymph to hemolymphatic target organs that include the bone marrow, spleen, and lymph nodes and to other internal organs such as the liver, kidney, and lungs. Respectively, hepatitis, glomerulonephritis, and pneumonitis may develop. Meronts in which asexually dividing merozoites develop are formed in the dog's tissues in the process of merogony. Two types of meronts are found in infected tissues, one containing approximately 20 to 30 slender micromerozoites and another containing up to four larger macromerozoites. Merozoites release from mature meronts, invade neutrophils and monocytes, and develop into gamonts in the process of gamontogony. Alternatively, merozoites can produce secondary meronts in the target tissues. Small monozyotic cysts of *H. canis* containing a single parasite have been described in tissues of naturally and experimentally infected dogs

Infectious Diseases of the Dog and Cat, 3rd Edition

(Fig. 74-3).¹⁰ The role of these cysts in the life cycle of *H. canis* has not been clarified. However, they resemble cysts described in lizards and snakes in which transmission by predation has been shown.⁹⁴

The tick, which serves as the definitive host, becomes infected by ingesting leukocytes containing gamonts when feeding on a parasitemic dog. Morphologically indistinguishable male and female *H. canis* gamonts release from the dog leukocytes within the tick gut, associate in syzygy, and differentiate in the process of gametogenesis to distinct gametes. After fertilization, the zygote divides and sporogony takes place with the formation of oocysts that release into the tick's hemocoel. The oocysts are large, spherical forms consisting of a membrane that envelops hundreds of sporocysts in which the infective sporozoites are found.⁶⁴ Sporozoites do not migrate to the feeding parts or salivary gland of the tick; therefore it must be ingested to infect the dog.

The life cycle of *H. canis* can be completed within 81 days. In an experimental transmission study, adult-stage *R. sanguineus* ticks were infective by ingestion to dogs 53 days after the ticks fed as nymphs on a naturally infected dog. Meronts were first detected in the experimentally infected dog's bone marrow 13 days postinoculation, and gamonts appeared in the blood, thereby completing the life cycle in 28 days.⁹

The pathogenesis of HCI is influenced by immunodeficient conditions, an immature immune system in young pups, a congenital defect, or concurrent infectious agents. Conditions that weaken the immune responses increase the susceptibility to new infection with *H. canis* or allow existing infections to reactivate. Co-infections with *Toxoplasma*, *Leishmania*, *Babesia*, or *Ehrlichia* predispose to clinical illness. In a litter of Dalmatians that were diagnosed with *H. canis* parasitemia, pups that contracted parvoviral enteritis demonstrated a significantly higher parasitemia than did their littermates.² In addition, treatment of experimentally infected dogs with an immunosuppressive dose of prednisolone was followed by the appearance of parasitaemia.⁹

Infection with *H. canis* elicits a distinct humoral immune response during the early stages of the disease.^{9,11} No information is currently available on the cellular response to HCI; however, because *H. canis* is an intracellular parasite, cell-mediated immunity probably constitutes a major role in the immune mechanism mounted by the host against HCI.

74.1.4 Clinical Findings

74.1.4.1 Dogs

A variety of clinical presentations is associated with HCI, ranging in severity from an incidental hematologic finding in an apparently healthy dog to a debilitating and life-threatening illness. A low level of *H. canis* parasitemia with gamonts found in less than 5% of neutrophils is the most common presentation of HCI. It is usually associated with an asymptomatic to mild disease. A high parasitemia sometimes approaching 100% of neutrophils with a leukocytosis is usually associated with a severe disease. High parasitemia rates are frequently found with extreme leukocytosis, reaching as high as 150,000 leukocytes/ μ l of blood.^{6,14} The mechanism causing this elevation in leukocytes, most commonly in neutrophils, has not been elucidated.

700

702

Fig 74-2 Stages in the life cycle of *H. canis*. **A**, Infected tick is ingested by the dog. **B**, Sporozoites are freed from the sporocyst in the dog's intestine, **(C)** penetrate the gut wall and reach the hemolymphatic target tissues (e.g., bone marrow) hematogenously or via the lymph. **D**, Merogony occurs in the target tissues, producing meronts containing **(E)** macromerozoites which can be released from the meront to invade new host cells to form secondary meronts containing macro- or micromerozoites. **F**, The secondary "wheel-spoke" shaped meront releases micromerozoites which invade myeloid cells to form gamonts, or alternatively produce further generations of meronts. **G**, Gamontogony occurs with a developing gamont in a neutrophil. Neutrophils with mature gamonts circulate in the blood. **H**, Gamonts are taken up by a tick during a blood meal. **I**, Morphologically indistinguishable male and female gamonts are released in the tick's gut, and associate in syzygy. Male and female gametes transform during gametogenesis prior to fertilization and produce a zygote. Sporogonic development in the gut leads to the formation of large oocysts found enveloping numerous sporocysts. Oocysts release into the hemocoel, and each sporocyst within them contains the infective sporozoites. (Courtesy University of Georgia, Athens, Ga.)

CHAPTER 74 Hepatozoonosis

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 74-3 A monozytic tissue cyst of *H. canis* in splenic tissue of a naturally infected dog (H and E stain, ×500).

In a case-control study of 100 dogs with HCI, dogs were categorized into low and high parasitemia groups. Eighty-five percent of the dogs had a low parasitemia level and 15% had a high number of circulating parasites.¹⁴ Dogs with low parasitemia were more anemic and had lower platelet counts than did the control dogs with other disease conditions. However, dogs with high circulating parasite numbers suffered mainly from fever, lethargy, weight loss, anemia, and hyperglobulinemia. The high numbers of circulating gamonts, in some cases ranging between 50,000 and 100,000 gamonts/μl of blood, are indicative of the large extent of tissue parasitism present in highly infected dogs. Tissue meronts produce the numerous merozoites that eventually invade leukocytes. The load of blood and tissue parasites present in dogs with high parasitemia levels takes its toll by demanding nutrients and exerting tissue injury. This finding explains the weight loss leading to cachexia and the profound lethargy observed in this subgroup of infected dogs.

Concurrent infections involving *H. canis* and other canine pathogens are common. Some of the reported co-infecting organisms, including *Ehrlichia canis* (Chapter 28)⁸⁶ and *Babesia canis* (Chapter 77),⁵⁴ are transmitted by the same tick vector, *R. sanguineus*, and are likely to be found in dogs with tick infestations in areas where these diseases are endemic in the dog population. Other pathogens reported to be involved in concurrent infections include parvovirus, canine distemper, *Anaplasma phagocytophilum*, *Anaplasma platys*,⁵⁴ *Toxoplasma gondii*,⁴² and *Leishmania infantum*.^{54,89} Co-infections may influence the susceptibility to establishing a new infection or the progression of an existing one.^{2,39,42} In the case of concurrent infection, clinical signs attributed to HCI must be interpreted cautiously and separated from manifestations of the concomitant pathogen.

74.1.5 Diagnosis

The pathogenesis, vectorial capacity, tissue tropism, and clinical signs associated with HCI differ from *H. americanum* infection. *H. canis* is found primarily in hemolymphatic tissues, whereas *H. americanum* infects

Infectious Diseases of the Dog and Cat, 3rd Edition

mainly muscular tissues, causing myositis and lameness. The principal differences between these two infections are summarized in [Table 74-1](#).

74.1.5.1 Clinical Laboratory Findings

Anemia is the most common hematologic abnormality in HCI and has been reported in the majority of HCI cases.^{14,40,54} The anemia is, in most cases, normocytic normochromic and occasionally regenerative.

The leukocyte count is usually normal when parasitemia is low and is elevated in dogs with high parasitemia. Extreme neutrophilia reaching 100,000 neutrophils/ μ l blood occurs in some cases with high parasitemia ([Fig. 74-4](#)). Thrombocytopenia is present in approximately one third of the dogs with HCI and is, in some cases, associated with concurrent canine ehrlichiosis. Serum chemistry abnormalities include hyperproteinemia with hyperglobulinemia and hypoalbuminemia and increased creatine kinase (CK) and alkaline phosphatase (ALP) activities. Electrophoresis of serum proteins from the sera of hyperglobulinemic dogs revealed polyclonal gammopathy.^{14,39}

74.1.5.2 Organism Identification

Microscopic detection of *H. canis* gamonts in Giemsa- or Diff-Quik–stained blood smears is the most common method for diagnosis of HCI. The concentration of organisms increases with the severity of the illness. The gamonts are ellipsoidal in shape and measure approximately $11 \times 4 \mu\text{m}$ ([Fig. 74-5](#)) and are found in the cytoplasm of neutrophils and rarely in monocytes. Gamonts are enveloped in a thick membrane ([Fig. 74-6](#)) and are often situated in the center of the neutrophil and compress its lobulated nucleus toward the cell membrane.¹⁰²

H. canis meronts can be detected in histopathologic specimens or in cytologic preparations made from aspirates or touch impressions of hemolymphatic tissues. Meronts are round to oval and are approximately $30 \mu\text{m}$ in diameter. Immature meronts appear as round opacities filled with globular foamlike material. As the meront matures, basophilic-staining chromatin material forms as either 2 to 4 larger macromerozoites or more than 20 micromerozoites. The shaping micromerozoites align in a circle close to the meront wall around a central opaque core. The mature meront visualized in histopathologic specimens creates a typical “wheel spoke” form when the circle of micromerozoites is incised in cross-section through their mid-shaft ([Fig. 74-7](#)).

H. canis can also be identified in vector ticks. Mature oocysts can be seen even without magnification as small white globular forms in wet preparations of the hemocoel. The observation of oocysts is verified and differentiated from the tick's organs and salivary glands by microscopy of hemocoel smears as unstained wet preparations or as Giemsa-stained specimens ([Fig. 74-8](#)). Oocysts are enveloped in an easily torn membrane and contain hundreds of smaller oval sporocysts. Free sporocysts are often present scattered outside the oocyst, and infective sporozoites are packed as elongated slender forms within the sporocysts.

74.1.5.3 Serologic Testing

The indirect FA test and the enzyme-linked immunosorbent assay (ELISA) for the serodiagnosis of HCI using gamont antigen have been developed and are used mainly for epidemiologic studies.* Antibodies of the IgM and IgG classes were detectable in the sera of experimentally infected dogs as early as 16 and 22 days postinfection, respectively, peaked at 7 to 9 weeks, and persisted for more than 7 months.^{5,11,41}

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 74-1 *Comparative Characteristics of Hepatozoon canis and Hepatozoon americanum Infections*

VARIABLE	HEPATOZOON CANIS	HEPATOZOON AMERICANUM
Geographic distribution	Asia, Southern Europe, Africa, South America	Southern United States
Principal vector tick	Brown dog tick, <i>Rhipicephalus sanguineus</i>	Gulf Coast tick, <i>Amblyomma maculatum</i>
Major target organs	Spleen, bone marrow, lymph nodes	Skeletal muscles, myocardium
Common clinical examination findings	Fever, lethargy, weight loss	Gait abnormalities, fever, muscle hyperesthesia, mucopurulent ocular discharge, lethargy
Severity of clinical disease	Usually mild when parasitemia is low; a severe disease with large numbers of circulating gamonts	Severe
Hematologic findings	Anemia; extreme neutrophilia is infrequent and found in dogs with large numbers of circulating gamonts; circulating blood gamonts are common and found mainly in neutrophils and rarely in monocytes; parasitemia ranges from 1% to 100% of the neutrophils	Anemia; neutrophilia is common and often extreme; circulating blood gamonts are infrequent and usually found in less than 0.1% of the leukocytes
Radiographic findings	Nonspecific	Periosteal proliferation
Histologic findings	Hepatitis, splenitis, nephritis, and pneumonia associated with presence of <i>H. canis</i> meronts	Pyogranulomatous myositis
Unique morphologic features	"Wheel spoke" meront; small monozytic splenic tissue cysts	Large muscle "onion skin cysts"
Main diagnostic procedure	Demonstrating gamonts in blood smear	Muscle biopsy demonstrating tissue cysts and pyogranulomas associated with developing parasitic stages
Serologic tests	Indirect FA test, ELISA (gamont antigens)	ELISA (sporozoite antigens)

FA, Fluorescent antibody; ELISA, enzyme-linked immunosorbent assay.

Fig 74-7 *H. canis* meront containing micromerozoites forming a wheel-spoke shape in splenic tissue (H and E stain, ×400).

* References: 5, 12, 13, 38, 41, 46, 93.

74.1.6 Pathologic Findings

Pathologic descriptions of infected dogs range from reports on infrequent tissue meronts termed as incidental findings⁵⁰ to severe and occasionally fatal multiple-organ involvement.^{*} A considerable variation is found in the spectrum of lesions and the number of parasitic life forms. The major macroscopic lesions found in dogs with heavy infections include splenomegaly and hepatomegaly, with a diffuse pattern of small white necrotic foci 1 to 2 mm in diameter.^{6,43} Necrotic foci may be larger and nodular in appearance and are also found in other tissues, including the pancreas and on the pleura.^{6,14,42} Pneumonia may be evident, and lymph nodes are typically enlarged.

Histopathology reveals a varying number of developing or mature meronts with their “wheel spoke” pattern in the affected tissues. These meronts are associated with a mild inflammatory response in some cases, ranging to severe responses in others.⁶⁷ Focal splenic necrosis is associated with *H. canis* merogony in red and white pulp regions, with white pulp necrosis located primarily in lymphoid follicles.⁴³ Hepatitis with Kupffer cell hyperplasia and mononuclear and neutrophil infiltration is associated with developing meronts in the liver.^{14,67} The presence of *H. canis* in the lung is associated with interstitial pneumonia and the thickening of alveolar septa with inflammatory cell infiltrates. Renal lesions include glomerulonephritis and interstitial nephritis with multifocal necrosis. Mild to extensive parasitism with meronts and developing gamonts is described in the lymph nodes and bone marrow.^{14,67}

Infectious Diseases of the Dog and Cat, 3rd Edition

* References: 6, 14, 42, 43, 67.

74.1.7 Therapy

The current treatment protocol for HCI is imidocarb dipropionate at 5 to 6 mg/kg (2.5 to 3.0 mg/lb), subcutaneously or intramuscularly, every 14 days, until gamonts are no longer present in the blood smears. One or two injections may suffice; however, the elimination of gamonts in heavy infections using imidocarb dipropionate may require treatment for 8 weeks or longer.¹⁴ Oral doxycycline at 10 mg/kg/day (5 mg/lb/day) for 21 days is also frequently used in combination with imidocarb dipropionate to treat potential or identified tickborne co-infections. No controlled studies on the therapy of HCI have been published.

The rate of survival of treated dogs with a low *H. canis* parasitemia is generally good and is frequently dependent on the prognosis of any concurrent disease, if present. The prognosis for dogs with a high parasitemia is guarded. Only 7 of 15 dogs (47%) with a high parasitemia survived 2 months despite specific treatment.¹⁴

74.1.8 Prevention

Prevention of HCI should consist of an effective control of vector ticks on dogs and in the environment using *external* parasiticides. Dogs must be prevented from ingesting ticks while grooming or scavenging. To prevent congenital transmission, infected dams should be treated effectively before being bred. Until the certainty that HCI may be transmitted by ingestion of infected tissues is reached, dogs in endemic areas should be prevented from eating raw or prey meat.

Infectious Diseases of the Dog and Cat, 3rd Edition

74.1.9 Public Health Considerations

The spectrum of natural hosts for HCl is not currently known. Only one report of infection with a *Hepatozoon* sp. in a person from the Philippines has been issued.¹⁹ This patient was anemic and icteric, and gamonts were detected in the blood. However, no parasites were found in liver and bone marrow biopsies. Although the zoonotic importance of *H. canis* is not known, and it is unlikely to be a significant pathogen in immunocompetent people, caution should be used when handling infected dogs infested with ticks or when removing ticks from dogs. 704 705

74.2 FELINE HEPATOZOONOSIS

Gad Baneth

Hepatozoonosis of domestic cats has been reported from India,⁸⁵ South Africa,⁹⁵ Nigeria,⁵⁷ the United States,²⁹ Israel,^{3,7,51} and France.¹⁸ The species of *Hepatozoon* that infect cats has not been identified. Whether only a single species is found in cats and whether it is similar to any species described in other animals is unknown. The vector of feline hepatozoonosis (FeHPZ) is also unknown. See Cats and Wild Carnivores, under Etiology earlier in this chapter, for the host range of reported infections.

FeHPZ is associated with infection of muscle tissues. *Hepatozoon* meronts have been identified in the myocardium and skeletal muscles of cats with hepatozoonosis,¹⁸ and elevated activities of the muscle enzyme CK were found in the majority of cats with FeHPZ in a retrospective study of this disease.³ Retroviral diseases are frequently found in association with FeHPZ and appear to be a predisposing factor. Feline immunodeficiency virus and feline leukemia virus (FeLV) were detected in four of six cats reported with FeHPZ from Israel and in two cats from France.^{3,18}

A wide variety of clinical signs has been described in cats with FeHPZ.* In a parasitemic cat from Israel, weakness, hypersalivation, lingual mucosal ulceration, and lymphadenomegaly were observed.⁷ The cat was treated with doxycycline and recovered. Two parasitemic cats from France that also had positive test results for FeLV had lethargy, anorexia, anemia, and thrombocytopenia.¹⁸ A cat from Hawaii had weight loss, ulcerative glossitis, pyrexia, progressive anemia, serous ocular discharge, and icterus.²⁹ The cat also had cytologic evidence of liver infection consistent with hepatozoonosis. The diagnosis of FeHPZ is usually performed by detection of gamonts in blood smears. The gamonts are located in the cytoplasm of neutrophils, have an ellipsoidal shape, and possess a round or pleomorphic nucleus (Fig. 74-9). The level of parasitemia is frequently low with less than 1% of the neutrophils containing gamonts. FeHPZ has been treated with the oral administration of doxycycline at 5 mg/kg (2.5 mg/lb)⁷ or oral oxytetracycline at 50 mg/kg (25 mg/lb) twice daily with a single dose of oral primaquine at 2 mg/kg (1 mg/lb).⁹⁵

74.3 HEPATOZOON AMERICANUM INFECTION

Douglass K. Macintire

Nancy A. Vincent-Johnson

Infectious Diseases of the Dog and Cat, 3rd Edition

Thomas M. Craig

74.3.1 Etiology and Epidemiology

All canine infections were once attributed to *H. canis* because of the similar appearance of *Hepatozoon* gamonts in canine white blood cells. In 1997, however, a new species, *H. americanum*, was identified based on differences in tissue stages, tick vector, clinical syndrome, ultrastructure, geographic distribution, and genetic and antigenic characteristics.^{4,100} Table 74-1 compares the clinical features of *H. canis* with *H. americanum*.

Fig 74-9 *Hepatozoon* sp. gamont in the cytoplasm of a neutrophil from a domestic cat. The blood smear was stained with Giemsa (×500).

Fig 74-10 Map showing known distribution of reported cases of *H. americanum* infection. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

In the United States, hepatozoonosis was first described in the Texas Gulf Coast in 1978.²³ Since that time, it has been reported also in Louisiana, Alabama, Georgia, Mississippi, Oklahoma, Tennessee, and Florida^{59,61} (Fig. 74-10). The definitive host for *H. americanum* is the Gulf Coast tick, *Amblyomma maculatum*.^{63,30} The geographic distribution of this tick was once confined to the warm, humid areas of the Texas gulf coast, but the range of this tick now has expanded as far north as Kansas and Kentucky.⁹¹ *H. americanum* infection appears to be an emerging disease that is spreading north and east from the area where it was initially detected. In addition to dogs, *H. americanum* or a similar organism has been diagnosed in coyotes, bobcats, and ocelots in the southern United States by identifying cysts or meronts in muscle or gamonts in blood smears.^{23,52} Whether the hepatozoonosis reported in dogs from Brazil^{40,78,79} was caused by *H. canis* or *H. americanum* is uncertain.

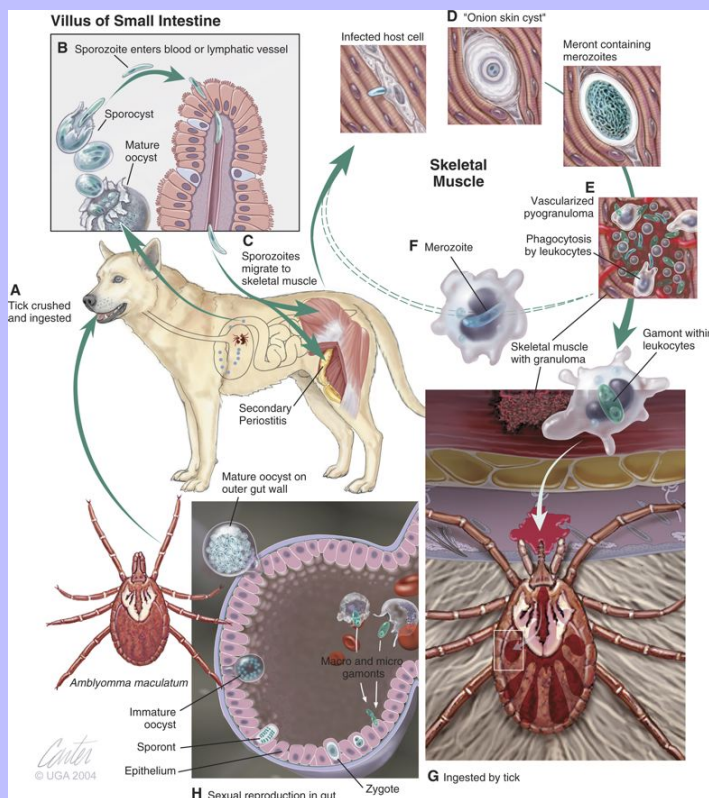

In contrast to *H. canis*-infected dogs, most dogs with *H. americanum* exhibit severe clinical signs even in the absence of concurrent disease or immunosuppression.⁵⁹ Because the parasite appears to be poorly adapted to dogs as a natural host, *H. americanum* is likely a natural parasite of some other species in the wildlife reservoir. Dogs become an accidental host after ingesting infected ticks. In the United States, the wildlife reservoir for domestic dogs infected with *H. americanum* has yet to be elucidated.

705

707

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 74-11 Stages in the life cycle of *H. americanum*. **A**, Infected tick is ingested by the dog. **B**, Sporozoites are freed from the sporocyst in the dog's intestine and penetrate the gut wall. **C**, They migrate to the skeletal and cardiac muscle target tissues hematogenously or via the lymph where they lodge in a presumed phagocytic cell between myocytes. **D**, Concentric layers of mucopolysaccharide material (onion skin) are deposited around the cyst. Some remain dormant while others undergo merogony forming meronts containing many merozoites. **E**, Upon maturation the meront ruptures releasing merozoites and induce a pyogranulomatous inflammatory reaction. Migrating phagocytes ingest the organisms. **F**, The ingested organism can circulate to other sites and continue asexual cycle. Others enter circulating phagocytes (monocytes or neutrophils) and transform into gamonts. **G**, Infected leukocytes are ingested by *Amblyomma* tick. **H**, Syngamy (sexual cycle) occurs in the tick gut epithelium producing macro- and microgamonts which fuse to form a zygote that matures to an oocyst. See text. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

The life cycle is similar to that of *H. canis*; however, notable differences exist (Fig. 74-11). In contrast to *H. canis*, the primary tissue sites for development of meronts in dogs with *H. americanum* infection are skeletal and cardiac muscle.⁸⁰ Infective sporozoites ingested by the dog are transported to striated muscle and other target organs where they develop within an unidentified host cell, which is most likely a phagocytic cell that initially lodges between myocytes.^{81,83} Concentric layers of a mucopolysaccharide material are deposited around the host cell to form a large cystic structure of 250 to 500 µm diameter. This structure has been referred to as an “onion skin cyst” and is the most common tissue stage of *H. americanum* found in infected dogs. Some cysts appear to go into a dormant state, while others undergo merogony. On maturation, numerous merozoites are released from the ruptured cyst, inducing a severe inflammatory response. Migration of neutrophils and monocytes into the area results in the formation of a pyogranuloma where the meront once existed. The pyogranuloma becomes highly vascularized, and inflammatory cells that have phagocytized single zoites return to circulation where they may travel to distant sites to continue the asexual cycle or may become circulating gamonts that can complete the life cycle when ingested by *A. maculatum* ticks feeding on the dog. In experimental infections, completion of the life cycle from ingestion of infected ticks to development of circulating gamonts can occur in as few as 35 days.⁸¹ In the tick, 42 days are needed for the organism to develop into mature oocysts that are present in the hemocoel of newly molted adults.⁶⁴ Experimental infections have been produced in both dogs and coyotes fed infected *A. maculatum* ticks.⁵³

The primary mode of transmission of *H. americanum* is through ingestion of the *A. maculatum* tick.³¹ Recent studies have shown that experimentally infected larval ticks are infectious to dogs after molting to nymphs.³⁰ Adult-stage ticks that have acquired infection at the nymph stage are also infectious to dogs. Gulf Coast tick larvae and nymphs feed primarily on ground-inhabiting birds and small mammals, while adults feed on larger wild and domestic mammals. This wide range of potential intermediate hosts can allow the organism to maintain an endemic life cycle in the geographic distribution area of the *A. maculatum* tick. The number of different species of animals that are susceptible to infection with *H. americanum* is not known, nor is the number of species that serve as the natural reservoir of disease.

In utero or congenital transmission of *H. americanum* from dam to puppies has not been documented but is probable given that it has been shown to occur with *H. canis*.²³ Also suggested is that dogs may potentially become infected by eating animals that have tissue stages of the organism. Although this type of transmission has not been proven, it does occur with other species of *Hepatozoon* and would seem plausible for *H. americanum* as well.

The geographic distribution of *H. americanum* parallels that of the definitive host, *A. maculatum*. Researchers at Auburn University, Auburn, Alabama, and Oklahoma State University, Stillwater, Oklahoma, were unable to transmit the disease with *R. sanguineus* or *Dermacentor* spp. ticks but were able to transmit the disease readily with *A. maculatum* ticks.^{31,97}

The occurrence of hepatozoonosis appears to be seasonal in the warmer months or in early fall when dogs are most likely to be exposed to ticks. Dogs with *H. americanum* usually exhibit waxing and waning clinical signs that occur throughout the year as repeated cycles of asexual reproduction and pyogranulomatous inflammation take place.

Infectious Diseases of the Dog and Cat, 3rd Edition

74.3.2 Pathogenesis

The progression of *H. americanum* infection in dogs from ingestion of sporozoites in ticks until the onset of clinical signs has been investigated in experimentally infected dogs⁸¹ and coyotes.⁵³ The earliest lesions are seen at 3 weeks postinfection, when the organism can be observed within a host cell located between myocytes. As the zoite matures, the host cell produces the layers of mucopolysaccharides that surround the host cell and protect it from the dog's immune system. No inflammatory response is associated with the organism when it appears as the onion skin cyst. Clinical signs occur when the cyst ruptures inducing severe pyogranulomatous myositis. Although some cysts rapidly undergo merogony, others can apparently remain dormant for years after the initial infection. Activation of these cysts and continued reproduction of the organism through repeated cycles of merogony result in the waxing and waning course of the disease and the occurrence of relapses following treatment. A prolonged infection may result from a single infecting episode perpetuated by repeated asexual cycles. Cysts have been found in muscle biopsies taken from dogs for up to 5 years after the initial infection.³⁴ Pyogranulomatous myositis in muscles adjacent to bones may stimulate a marked periosteal reaction along bone surfaces, especially in younger animals. Chronic infection causes persistent antigenic stimulation and may result in vasculitis, immunoproliferative glomerulonephritis, and amyloid deposition in various organs. Prolonged infection usually results in chronic cachexia and progressive weight loss and muscle wasting with death generally occurring within 12 months postinfection.

74.3.3 Clinical Findings

74.3.3.1 Dogs

In contrast to the usually mild disease seen with HCl, *H. americanum* causes a debilitating and usually fatal disease. Antibiotic unresponsive fever (39.3° to 40.9° C [102.7° to 105.6° F]), cachexia, depression, generalized muscle atrophy, and hyperesthesia (especially noticeable over the paraspinal regions), purulent ocular discharge, and mild anemia are seen in most dogs.²³ The clinical signs may wax and wane with the degree of pyogranulomatous inflammation. Many dogs have been treated for fever of unknown origin with several courses of antibiotic therapy before it became evident that the waxing and waning course is not a positive response to treatment. Chronic weight loss most likely results from muscle atrophy and the increased caloric demands associated with the prolonged inflammatory state. Mucopurulent ocular discharge is a fairly consistent finding and may be secondary to pyogranulomatous inflammation of extraocular muscles or destruction of the lacrimal gland. Approximately one third of the dogs with matted eyes have decreased tear production on a Shirmer tear test.⁵⁹ Other occasionally reported ocular abnormalities have included focal retinal scarring, hyperpigmentation and hyperreflectivity, mild papilledema, and uveitis with active inflammatory fundic lesions.²³

The pain that accompanies the myositis may show as cervical, back, joint, or generalized pain. Hyperesthesia, stiffness, neck guarding, and fever can easily be mistaken for meningitis or diskospondylitis, but analysis of cerebrospinal fluid is usually unremarkable. Gait abnormalities can include stiffness, generalized weakness, rear-limb paresis and ataxia, and an inability or unwillingness to rise.

The stiffness and reluctance to move cause many dogs to assume a “master's voice” stance (Fig. 74-12). Pain, particularly in the lumbar region, may resemble traumatic or degenerative disease of the spine. Because 707
of fever, lumbar pain, and leukocytosis, a few cases were initially suspected of having pyelonephritis or 708

Infectious Diseases of the Dog and Cat, 3rd Edition

closed pyometra.²³ Dogs may have a history of polyuria and polydipsia, especially if secondary glomerulonephritis or amyloidosis is present. Less common clinical signs include transient bloody diarrhea, abnormal lung sounds, cough, pale mucous membranes, and lymphadenomegaly.²³ Despite progressive weight loss and muscle wasting, many dogs continue to maintain a fairly normal appetite.

Fig 74-12 Six-month-old terrier mix with hepatozoonosis. Notice the extreme emaciation and the master's voice posture.

74.3.4 Diagnosis

74.3.4.1 Clinical Laboratory Findings

The most consistent laboratory abnormality for dogs with *H. americanum* is an elevated leukocyte count that commonly ranges from 20,000 to 200,000 cells/ μ l.⁵⁹ Infection with *H. americanum* is usually associated with a mature neutrophilia, but occasionally a mild to moderate left shift may be present. A mild normocytic, normochromic, nonregenerative anemia has been a consistent finding, with reported cases of hepatozoonosis. The platelet count is typically normal to elevated, and marked thrombocytosis (up to 916,000 platelets/ μ l) has been evident in some dogs.⁶¹ The finding of thrombocytopenia should prompt the clinician to suspect concurrent infection with other tick-borne diseases such as ehrlichiosis ([Chapter 28](#)), Rocky Mountain spotted fever ([Chapter 29](#)), or babesiosis ([Chapter 77](#)).

The most common abnormalities detected on serum chemistry panels in dogs with *H. americanum* include mildly increased serum ALP activity, hypoglycemia, and hypoalbuminemia.⁵⁹ The increase in serum ALP activity may be associated with the periosteal inflammation that occurs secondary to myositis. Hypoglycemia, generally in the range of 40 to 60 mg/dl, is thought to be the result of in vitro metabolism of glucose by white blood cells. When sodium fluoride is used as the anticoagulant to block glucose metabolism by the cells, the blood glucose value is usually in the normal reference range. Hypoalbuminemia is a

Infectious Diseases of the Dog and Cat, 3rd Edition

consistent finding and may be associated with decreased protein intake, chronic inflammation, or renal loss. Serum urea values are usually low unless significant renal damage has occurred from chronic disease. Decreased serum urea values may represent reduced protein intake or disordered protein metabolism secondary to negative nitrogen balance and production of inflammatory proteins. Low serum urea values may contribute to the polyuria seen in some dogs because of a reduced renal medullary concentration gradient. With chronic disease, dogs may develop protein-losing nephropathy with high urine protein-creatinine ratios secondary to glomerulonephritis or renal amyloidosis. Although hypoglycemia, hypoalbuminemia, and low serum urea levels are often associated with liver disease, serum bile acids are usually normal or only slightly elevated in dogs with *H. americanum* infection. Despite the muscle inflammation, CK activity is almost always within reference limits. Hyperglobulinemia is relatively uncommon. Generalized polymyopathy may be found with electromyography. Lymph node aspirates are characterized microscopically by hyperplasia. Results of synoviocentesis analysis reveal nonseptic inflammation.⁶¹ Bone marrow cytologic findings are granulocytic hyperplasia and erythroid hypoplasia with a high myeloid erythroid ratio.

Fig 74-13 Radiograph of the pelvis and lumbar vertebrae of a dog with periosteal new bone proliferation associated with *H. americanum* infection.

Infectious Diseases of the Dog and Cat, 3rd Edition

74.3.4.2 Radiography

Periosteal bony lesions have not been described in dogs infected with *H. canis* and have only been reported in dogs from North America, with the exception of one dog in Japan.²³ For dogs infected with *H. americanum*, radiographic findings may range from spectacular to nonexistent. Periosteal bone proliferation has been associated with the attachment of muscle on most bones of the body except the skull (Figs. 74-13 and 74-14). Bony changes have been noted in the vertebrae, pelvis, radius, ulna, humerus, femur, fibula, and tibia.^{27,59} Not all infected dogs develop this unique lesion. Radiographic lesions are more common in younger dogs (younger than age 1 year) than they are in older dogs. Whether the radiographic changes are associated with rapid skeletal growth or are indicative of a more severe infection in the young is unknown. Morphologically, the lesions resemble hypertrophic osteopathy.⁸³

Radiographs can be used as a screening test to provide supportive data for a diagnosis of hepatozoonosis. Pelvic radiographs or radiographs of the long bones may show subtle irregular periosteal exostoses or smooth lamellar thickening of the periosteum. Nuclear bone scintigraphy can detect changes in the bone beginning between 35 and 67 days after infection.²⁷

708

709

Fig 74-14 Radiograph of femur, tibia, and fibula of a dog infected with *H. americanum*.

Fig 74-15 Gamonts of *H. americanum* in circulating neutrophils appear identical to *H. canis* gamonts (Giemsa, $\times 1200$).

74.3.4.3 Organism Identification

In contrast to HCl, the gamonts of *H. americanum* are difficult to find because usually less than 0.1% of neutrophils or monocytes are infected. When seen, the gamonts of *H. americanum* appear as a light blue to clear oblong capsule measuring approximately $8.8 \times 3.9 \mu\text{m}$ with a faintly staining nucleus (Fig. 74-15). Special staining techniques have been advocated, but they are laborious and often unrewarding because of the low degree of parasitemia. Examination of buffy coat smears may increase the chance of finding a gamont-infected cell.

Muscle biopsy is a convenient and more consistent means of establishing a diagnosis of *H. americanum* in infected dogs (see Pathologic Findings). Two or three small pieces of muscle ($2 \times 2 \text{ cm}$) are taken from the biceps femoris or semitendinosus muscle with the dog under general anesthesia. Cysts, meronts, and pyogranulomas with zoite-containing neutrophils and monocytes are diagnostic of *H. americanum* infection. Myositis is a less specific but common finding. False-negative results sometimes occur when a sample does not contain any lesions, but this rarely happens because of the extremely high number of organisms in infected dogs. Taking several samples or repeating the procedure sequentially may reduce the probability of obtaining a false-negative result. Xenodiagnosis, whereby adult ticks are examined for infection after feeding at the nymph stage on a suspected dog, is the most sensitive means of detection; however, it is practical only in an experimental setting.³⁴

Fig 74-16 ÒOnion skin cystÓ of *H. americanum*. Concentric layers of a mucopolysaccharide material surround a host cell to form a large cystic structure in the skeletal muscle (H and E stain, ×400).

74.3.4.4 Serologic Testing

Researchers at Oklahoma State University have developed an ELISA method for *H. americanum* using sporozoites as the antigen. This test showed a 93% sensitivity and 96% specificity when compared with muscle biopsy results.⁶⁵

74.3.5 Pathologic Findings

Consistent gross findings in dogs with *H. americanum* are cachexia and muscle atrophy. Roughened, thickened bone surfaces may be seen. Grossly, pyogranulomas may appear as multiple, 1 to 2 mm, white to tan foci scattered diffusely throughout muscle and other tissues. Microscopically, the cysts (Fig. 74-16), meronts (Fig. 74-17), and pyogranulomas (Fig. 74-18) are found primarily in skeletal and cardiac muscle but may also be found sporadically in other tissues, including adipose tissue, lymph node, intestinal smooth muscle, spleen, skin, kidney, salivary gland, liver, pancreas, and lung. An immunohistochemical staining procedure has been developed to identify specifically muscle cysts.⁸⁴ Vascular changes in various organs include fibrinoid degeneration of vessel walls, mineralization and proliferation of vascular intima, and pyogranulomatous vasculitis. Renal lesions are common and include focal pyogranulomatous inflammation with mild glomerulonephritis, lymphoplasmacytic interstitial nephritis, mesangioproliferative glomerulonephritis, and occasionally amyloidosis. Amyloid deposits can also be found in the spleen, lymph nodes, small intestines, and liver. Less common findings include pulmonary congestion, splenic coagulative necrosis, lymphadenomegaly, and congestion of the gastric mucosa.

709

Table 74-2 describes treatment regimens for hepatozoonosis.

Treatment of *H. americanum* has been frustrating because no therapy is effective in eliminating the tissue stages of the organism. Palliative therapy with nonsteroidal antiinflammatory drugs at standard dosages can provide immediate relief from fever and muscle pain while definitive antiprotozoal therapy is initiated. Remission of clinical signs can usually be obtained quickly by administering a combination of trimethoprim-sulfadiazine, clindamycin, and pyrimethamine (TCP combination) for 14 days. (See Table 74-2 for dosages.) Although the clinical response is dramatic, it is often short-lived. Most dogs relapse within 2 to 6 months following treatment because of continued release of merozoites into muscle and other tissues as the meronts undergo replication and development. No treatment is available that is able to penetrate the host cell and arrest development of the meronts when they are in the cystic stage. Although response to treatment is generally good with subsequent relapses, they may recur more frequently over time. Persistent recurrent infections can lead to glomerulonephropathy, amyloidosis, vasculitis, and chronic cachexia.

A relatively new treatment to assist in preventing clinical relapses is decoquinat (Deccox), an anticoccidial drug for food animals. This drug is given daily for 2 years once clinical signs have resolved (see Table 74-2). In some cases, mild relapses can occur even when dogs are receiving decoquinat. If fever and leukocytosis are present, another course of antiprotozoal therapy is warranted. Decoquinat is available as a livestock feed additive at a concentration of 27.2 grams of decoquinat per pound of premix. The powder can be mixed into moist dog food at a rate of 0.5 to 1.0 teaspoons per 10 kg body weight and fed twice daily.

Fig 74-17 A mature *H. americanum* meront just before release of merozoites. Note the lack of inflammation surrounding the cystic structure (H and E stain, $\times 1200$).

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 74-2 Therapy for *Hepatozoon americanum* Infection in Dogs

DRUG ^a	DOSE ^b (MG/KG)	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)
TCP combination:	15	PO	12	14
trimethoprim-sulfonamide	10	PO	8	14
and clindamycin and	0.25	PO	24	14
pyrimethamine and	10–20	PO	12	730
decoquinate				

TCP, Trimethoprim-sulfadiazine, clindamycin, and pyrimethamine; PO, by mouth.

a See Drug Formulary, [Appendix 8](#), for additional information on each drug.

b Dose per administration at specified interval.

In the past, the prognosis for dogs with *H. americanum* infection was guarded to poor.²³ With the advent of the TCP combination therapy followed by daily decoquinate administration, the prognosis has markedly improved. Relapses are less frequent and severe, and glomerulonephritis and amyloidosis are less common. In a comparison of treatment protocols, the 2-year survival rate for dogs receiving only antiprotozoal therapy was 12.5% but increased to greater than 84% survival for dogs receiving antiprotozoal treatment followed by long-term decoquinate.⁶⁰ Dogs treated with TCP combination therapy followed by decoquinate for 2 years have been disease free for over 5 years.

74.3.7 Prevention

Control of ticks with an effective acaricide is important to limit the spread of disease. The transmission of *H. canis* occurs only transtadially; transovarial transmission is unknown. Environmental control of the vector by preventing it from feeding on infected dogs therefore will help prevent spread. Home or kennel environments should be sprayed on a routine basis. Regular dipping of dogs from infested premises will kill any ticks feeding at that time.

Although transmission by ingestion of infected tissues has not been proven, it does occur with other species of *Hepatozoon*. For this reason, dogs should not be fed raw meat or organs from wildlife in endemic areas.

710

711

Fig 74-18 Pyogranuloma associated with the invasion of merozoites released from a cyst in a dog with *H. americanum*. Phagocytized merozoites can either reenter circulation to become gamonts or form a new onion skin cyst.

Infectious Diseases of the Dog and Cat, 3rd Edition

74.3.8 Public Health Considerations

Only one report of human infection with a *Hepatozoon* spp. has been issued²³ (see previous discussion on *H. canis* infection). Transmission of *H. americanum* to people is unlikely because the disease is transmitted by ingestion of a tick rather than by a tick bite. The danger of direct transmission from dogs to people is apparently low.

75 CHAPTER 75 Microsporidiosis

Peter J. Didier

Karen Snowden

Xavier Alvarez

Elizabeth S. Didier

75.1 ETIOLOGY

Microsporidiosis in dogs and cats is primarily caused by the obligate, intracellular parasite *Encephalitozoon cuniculi*, which is a member of the phylum Microsporidia. More than 1000 species of microsporidia—classified into approximately 100 genera—infect insects and members of all classes of vertebrates.^{6,23} Medically important species of the genus *Encephalitozoon* (*Encephalitozoon hellem*, *Encephalitozoon intestinalis* [previously named *Septata intestinalis*], and three strains of *E. cuniculi*)^{5,22,29,33} that have been described may infect dogs, cats, and birds.²³ Another microsporidian species, *Enterocytozoon bieneusi*, a common intestinal opportunistic parasite in patients with the acquired immunodeficiency syndrome (AIDS), has been identified in stool samples from cats, farm dogs, nonhuman primates, and numerous asymptomatic pigs.^{12,17,20,38} Although no disease from *E. bieneusi* or *E. intestinalis* has been described in dogs and cats, the zoonotic potential of these subclinical infections needs additional investigation by analysis of diagnostic materials.⁶⁶

Because *E. cuniculi* is the most commonly described microsporidian in pet animals, this chapter will focus primarily on this species. Mature spores of *E. cuniculi* are small and oval, measuring approximately 1.5 µm wide and 2.5 µm long. They contain the distinctive coiled polar tubule or filament-and-extrusion apparatus that distinguish microsporidia from all other organisms (Fig. 75-1). The polar tubule is used to propel the sporoplasm (containing the microsporidian nucleus) into the host cell. Spores also contain a posterior vacuole, ribosomes, endoplasmic reticulum, and Golgi-like membranes, but they lack mitochondria and peroxisomes. The spore coat contains an outer glycoprotein coat, a middle layer containing chitin, and an internal plasma membrane.²⁰

Infection of most mammalian hosts with *E. cuniculi* occurs by ingestion or inhalation of spores from contaminated urine or feces that are shed by infected hosts.^{6,23} Infection by transplacental transmission and traumatic inoculation have been reported as well.⁵⁰ Once internalized, infectious spores invade host cells by propelling the sporoplasm through the everting polar tubule by a process called *germination*. The sporoplasm of *E. cuniculi* develops within a host-cell-derived membrane-bound parasitophorous vacuole (Fig. 75-2). The organisms undergo schizogony (also called *merogony*), which is an asexual process of cell division or binary fission. During sporogony and maturation, organisms develop the spore coat and organelles (the polar tubule, endoplasmic reticulum, and polar cap). The host cells eventually rupture and release organisms that infect new cells or environmentally resistant spore forms, which are shed in the urine or feces.⁶ Typical organs of localized infection in dogs and cats include the kidney, liver, and brain.⁵⁰

Infectious Diseases of the Dog and Cat, 3rd Edition

75.2 EPIDEMIOLOGY

Natural infections with *E. cuniculi* have been described in a wide range of hosts, including rabbits, mice, cats, dogs, foxes, and people.^{6,23,50,52} Of the three strains (genotypes) of *E. cuniculi*, strain I has been identified in rabbits and people. Strain II has been identified in mice, rats, and blue foxes, and strain III has been found in dogs and people.^{11,21-23,41,66} Strain III has also caused fatal infections in nonhuman primates.⁴³ Differences in these isolates have been confirmed by protein electrophoresis, Western blot immunodetection, and small subunit ribosomal RNA (SSU rRNA) gene sequence analysis. Although epidemiologic information is sparse, one report suggests that *E. cuniculi* was transmitted to a dog groomer with AIDS.⁶⁶ However, strain I (primarily from rabbits) can infect mice, cats, and sheep in experimental situations.^{23,44,50} A comparison of isolates from people and rabbits suggests the infecting strain is zoonotic.^{13,14,23} A strain of *E. cuniculi* from a dog produced a subclinical infection in immunocompetent monkeys.^{23,54} Relatively few isolates of *E. cuniculi* are available for comparison, so the host specificity of the *E. cuniculi* strains is still unclear.

712

Fig 75-1 Electron microscopy of a mature *E. cuniculi* spore. Anterior polaroplast (*P*), loops of the polar filament (*F*) in longitudinal and cross-section views, nucleus (*N*), posterior vacuole (*V*) and electron-lucent spore wall are shown (bar = 200 nm). (From Shadduck JA, Bendele R, Robinson GA. 1978. Isolation of the causative organism of canine encephalitozoonosis, *Vet Pathol* 15:449-460. Used with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 75-2 Intracellular life cycle of *E. cuniculi* in the renal tubular epithelium. Diagram is based on light and electron microscopic examination of parasites. Spore is ingested or inhaled and penetrates the gut wall, entering the systemic circulation. Spore can spread to many organs, such as the kidney shown here. **A**, Mature spore uses polar tubule to propel its sporoplasm into host cell. **B-F**, Proliferative forms of parasite (*schizonts*) replicate within parasitophorous vacuole. Binary fission occurs during contact with membrane of intracellular vacuole. As maturation progresses, spores collect in center of vacuole. **D** and **E**, Parasitophorous vacuole containing spores and proliferative forms. These stages are visible under light microscope. **F**, Vacuole ruptures, releases its spores into renal tubule lumen, and is excreted in urine. (Courtesy University of Georgia, Athens, Ga.)

A few studies have been published on the prevalence rates of naturally acquired *E. cuniculi* infections.²³ In a group of stray dogs that were housed three per cage in a London kennel, 13.3% of the dogs were found to express specific antibodies to *E. cuniculi*.³⁰ In South Africa a serologic study of 220 serum samples submitted for clinical evaluation suggested a prevalence of 18% in domestic dogs.⁴⁹ Among 52 dogs with renal failure, 12 (23%) expressed specific antibodies for *E. cuniculi*, compared with 2 of 42 (5%) control dogs.⁴⁸ Based on the presence of specific antibodies, a prevalence of 70% was also reported in 50 dogs housed in kennels. This high prevalence may have been a result of confinement and closer contact to contaminated urine or feces.^{23,49} In an urban animal shelter, 6 of 20 dogs were found to be excreting microsporidial spores in the stools.³² In Norway, biochemical

712

713

Infectious Diseases of the Dog and Cat, 3rd Edition

testing did not identify antibody titers to *E. cuniculi* in sera from dogs of unknown health status.¹ Natural *E. cuniculi* infections of cats are rare, and no prevalence data have been published.⁵⁰

Clinically significant infections of *E. cuniculi* generally develop in neonatal and young puppies and are acquired by transplacental transmission and ingestion or inhalation of spores shed from the mother.^{23,50} Older dogs may become infected with microsporidia by inhalation or ingestion of spores from contaminated urine or feces or by ingestion of tissues from rabbits or mice infected with *E. cuniculi*.^{40,50} Experimental canine infections also may be transmitted by intraperitoneal (IP) inoculation, whereas kittens may be infected experimentally by intracerebral, IP, or oral inoculation. Cats and older dogs generally show few or no clinical signs of disease but do sporadically shed organisms in the urine. Younger dogs infected with microsporidia have clinical signs associated with renal disease.^{48,50} In experimental studies of other mammals, microsporidiosis has been chronic and asymptomatic in healthy immunocompetent animals but severe and lethal in T-cell-depleted animals.

75.3 CLINICAL FINDINGS

75.3.1 Dogs

Clinical signs in neonatal dogs appear within a few weeks postpartum, and several pups in a litter may have stunted growth and general unthriftiness.²³ As infection progresses, animals show signs of renal failure and neurologic abnormalities such as depression, ataxia, convulsions, and blindness.^{8,39,40,50} Animals may develop aggressive behavior consisting of viciousness, biting, and abnormal vocalizations. The high frequency of anti-*E. cuniculi* antibodies in dogs with azotemia suggests that *E. cuniculi* may contribute to chronic renal disease in dogs.^{48,50}

Clinical laboratory findings are available only for experimentally infected dogs.^{23,50,51} A normochromic, normocytic anemia is a consistent finding and may result from severe renal lesions with depression of erythropoietin production. In contrast, leukocyte numbers, especially those of lymphocytes and monocytes, are higher. Bone marrow is hypercellular, with a preponderance of large mononuclear cells. Serum biochemical findings include increased alanine aminotransferase and alkaline phosphatase concentrations (in the high normal to slightly elevated range), variable serum urea nitrogen and creatinine levels, and increased total serum protein levels. Cerebrospinal fluid (CSF) may have more protein and cells in animals with behavioral and neurologic signs and higher anti-*E. cuniculi* IgG levels in the CSF than in serum. Urinalysis may demonstrate hematuria and pyuria.

75.3.2 Cats

Clinical signs in feline encephalitozoonosis vary. Severe muscle spasms, superficial corneal infection with blepharospasm, depression, paralysis, and death have occurred in those with natural infections, but the results could not be duplicated in experimental trials.^{23,50} Clinical laboratory findings specifically for cats have not been reported.

75.4 DIAGNOSIS

Immunologically competent hosts produce specific antibodies to *E. cuniculi*, which can be detected by methods such as indirect fluorescent antibody (FA) staining and an enzyme-linked immunosorbent assay (ELISA).^{23,50} An

Infectious Diseases of the Dog and Cat, 3rd Edition

indirect FA titer greater than 1:20 or an ELISA titer of 1:800 or greater is considered to be positive for the presence of antibodies to *E. cuniculi*.^{23,30,49,50} However, serologic tests are not commercially available, and some are concerned about the diagnostic reliability of serologic tests in immunologically immature puppies or casually exposed hosts. Therefore, diagnostic methods have focused on detecting the microsporidian spores in urine, stool, and tissue specimens.

The small size and poor staining qualities of *Encephalitozoon* organisms have made them difficult to visualize with routine parasitologic and histologic techniques. They are easily missed with hematoxylin-eosin (H and E) staining, especially when few organisms are present.

Transmission electron microscopy (EM) has been considered the standard for the specific diagnosis of microsporidiosis. Presence of the polar tubule distinguishes microsporidia from other organisms (see Fig. 75-1).^{6,23,50} However, transmission EM is relatively insensitive, costly, and time consuming and requires technical expertise.^{18,23}

Cytologic examination of body fluids is extremely important when making a clinical diagnosis in animals with disseminated infections. Spores shed into the urine from parasitized renal tubular epithelial cells are readily identifiable in the sediment with Gram or Ziehl-Neelsen staining.^{23,26,28,50} Stained spores are gram-positive, whereas spores in the proliferative stages are gram-negative. Microsporidia in stool specimens are also difficult to distinguish from other gram-positive bacteria; however, indirect FA methods using monoclonal antibodies or hyperimmune polyclonal antisera can specifically identify microsporidia^{23,56} (Fig. 75-3, A), but reagents are not commercially available. When viewed with cross-polarizing filters, *Encephalitozoon* species and other microsporidia have a birefringent appearance, unlike the coccidians *Toxoplasma gondii* and *Isospora* species.

713

Chitin-staining fluorochromes (e.g., Calcofluor White 2MR, American Cyanamid, Princeton, N.J.) are useful for detecting the microsporidia, which stain as white to turquoise oval halos when viewed with ultraviolet (UV) microscopy (see Fig. 75-3, B).^{*} Microsporidia are easily stained with the modified trichrome stains (using tenfold higher concentrations of chromotrope 2R) and appear bright pink with a diagonal pink band and a clear posterior vacuole. Bacteria stain with the counterstain (see Fig. 75-3, C).[†] Yeasts also stain bright pink but lack a posterior vacuole, and they are usually larger and more round than the oval-shape microsporidia. However, these staining methods cannot be used to discriminate between species of microsporidia. Molecular identification by the polymerase chain reaction (PCR) may soon replace EM as the method of choice for confirmation of microsporidiosis because experimental studies suggest PCR is significantly more sensitive and specific.[‡]

75.5 PATHOLOGIC FINDINGS

Based on experimental infections, gross lesions of canine encephalitozoonosis include hepatomegaly, petechiae on multiple organs, patchy consolidation and edema of the lungs, fibrinous pericarditis, regional enteritis, focal myocardial degeneration, swollen kidneys, hemorrhagic cystitis, and splenomegaly.^{23,50} The kidney may contain

Infectious Diseases of the Dog and Cat, 3rd Edition

mild petechiae or severe cortical cysts and infarcts (Fig. 75-4). The brain may contain thrombosed meningeal blood vessels, focal encephalomalacia, and cystic spaces within the parenchyma. In naturally infected blue foxes, nodular thickening of the extramural coronary arteries and lymphadenomegaly have been seen.⁵⁰

Histologically, dogs and blue foxes with encephalitozoonosis consistently have nonsuppurative

meningoencephalitis (Fig. 75-5).^{23,39,50} Fibrinoid necrosis of small and medium-size arteries of the brain can result in thrombosis and encephalomalacia. Parasitophorous vacuoles develop in endothelial and glial cells.

714

Kidneys of dogs, cats, and foxes have multifocal nonsuppurative interstitial nephritis. Parasitophorous vacuoles with organisms are present in the renal tubular epithelia. In the heart, focal myocardial necrosis, vasculitis, and fibrinoid necrosis of small and medium-size arteries are associated with *E. cuniculi* in endothelial cells and smooth muscle cells. In experimental infections, livers of dogs and cats developed vascular fibrinoid necrosis, focal hepatic necrosis, and lymphoplasmacytic infiltration associated with *E. cuniculi* in hepatocytes, Kupffer's cells, and endothelial cells. In blue foxes, ocular lesions are attributable to arterial lesions of the short and long ciliary arteries and retinal vessels. Other nonspecific lesions include pulmonary edema, nonsuppurative interstitial pneumonia and enteritis, lymphadenomegaly, reticuloendothelial hyperplasia of the spleen, and hyperplasia of the bone marrow.⁵⁰

715

Small numbers of inflammatory cell and resident nuclei are blue (TO-PRO-3 dye). Background (gray) is differential interference phase contrast. *E. cuniculi* is stained with rabbit antiserum and secondary antibody linked to Alexa 468; endothelium is marked with isolectin B4 and Alexa 568 (bar = 5 μ m).

75.6 THERAPY

No treatment has been reported for either canine or feline encephalitozoonosis. In vitro experiments demonstrate that the antibiotic fumagillin inhibits the replicative ability of the organism without damaging the host cell, but the drug is toxic when used systemically in mammals.^{23,50} Topical fumagillin has successfully treated microsporidial keratitis in people infected with the human immunodeficiency virus (HIV). No information regarding its use in dogs and cats with microsporidiosis has been reported.^{19,23,24} An analogue of fumagillin, known as *TNP-470*, was effective in vitro and in vivo in mice with experimental intraperitoneal infections.⁹ Resveratrol, a natural compound in grapes, has sporicidal activity in vitro and was not toxic to cultured cells, suggesting a potential use for treatment.^{35a} The benzimidazole albendazole has successfully treated *Encephalitozoon* infections in patients with AIDS.^{3,11,19,23,42,55} No information regarding its use for treating dogs and cats with microsporidiosis has been published. *E. intestinalis* and only some *E. bienersi* strains, both of which can infect dogs, are susceptible to albendazole. In adult humans, the dosage is 400 mg every 12 hours for 4 weeks or longer. In vitro and in vivo studies suggest that the parasite is inhibited by antifolate drugs. Trimethoprim or pyrimethamine and sulfonamides alone or in combination with albendazole have effectively treated people with disseminated infections.^{23,25}

Infectious Diseases of the Dog and Cat, 3rd Edition

Clindamycin effectively treated a disseminated *Encephalitozoon*-like species infection in an immunocompromised person.³⁴ (See the Drug Formulary, [Appendix 8](#), for canine dosages and precautions.)

Table 75-1 Species of Microsporidia Infecting People and Animals

MICROSPORIDIA	HUMAN CONDITION	NATURALLY INFECTED ANIMALS
<i>Brachiola algerae</i>	Keratitis	Mosquitoes
<i>Brachiola connori</i>	Disseminated infection	Invertebrates
<i>Enterocytozoon bieneusi</i> ^a	Diarrhea, malabsorption, weight loss, rhinitis, bronchitis	Monkeys, swine, farm dogs, cats
<i>Encephalitozoon cuniculi</i>	Peritonitis, hepatitis, rhinosinusitis, seizures, nephritis, disseminated infection	<i>Strain I</i> : rabbits, humans; <i>strain II</i> : mice, blue foxes, rats; <i>strain III</i> : dogs, cats, humans, tamarins Foxes, rodents, monkeys, birds, cattle
<i>Encephalitozoon hellem</i>	Conjunctivitis, keratoconjunctivitis, rhinosinusitis, bronchiolitis pneumonia, disseminated infection	Budgerigars
<i>Encephalitozoon intestinalis</i> ^a	Diarrhea, disseminated infection pneumonia, cholecystitis, cholangitis	Dogs, goats, cattle, swine
<i>Pleistophora</i> species ^a	Myositis	Australian terrestrial mammals, insects, neon tetra fish
<i>Trachipleistophora hominis</i>	Myositis, keratitis, rhinosinusitis	Unknown
<i>Trachipleistophora antheiopoophthera</i>	Disseminated infection	Unknown
<i>Microsporidium</i> species ^b	Keratitis	Unknown
<i>Nosema ocularum</i> ^a	Keratitis	Invertebrates
<i>Vittaforma corneae</i> ^a	Keratitis, disseminated infection	Unknown

a Water and/or food contamination also reported in addition to known animal sources.

b Collective term for unclassified microsporidia.

75.7 PREVENTION AND PUBLIC HEALTH CONSIDERATIONS

Identification of several species of microsporidia in people and animals ([Table 75-1](#)) suggests the possibility of zoonotic transmission.^{12,14} In people with AIDS, *E. bieneusi*, *E. intestinalis*, and *E. hellem* are the most frequent causes of disease and probably result from opportunistic spread of endogenous microflora. In people infected with HIV, intestinal microsporidiosis is associated with male homosexuality and swimming pools, suggesting fecal-oral transmission by sexual and waterborne routes.³¹ However, one report describes a 10-year-old girl who underwent seroconversion to *E. cuniculi* after close contact with an infected puppy^{23,40}; transmission of *E. cuniculi* and *E. bieneusi* to a dog handler was suspected in another case.⁶⁶ No direct evidence proves that dogs infect people with microsporidia, people infect dogs, or both. Isolates of *E. cuniculi* strain III have been identified in dogs and immunocompromised individuals, suggesting that this species has a zoonotic potential, a common source of exposure, or both.⁴⁶

715

Maintaining sanitary conditions is important when handling suspected cases of encephalitozoonosis because environmentally resistant spores may be shed in urine or feces. Spores can readily be rendered uninfected by various disinfectants; the most commonly available are 2% phenol, 10% formalin, and 70% ethyl alcohol. Infectivity is unaffected by sonication, freezing and thawing, and pH levels ranging from 4 to 9. Infectivity of spores stored in neutral buffer at 4°C and 20°C persists for more than 24 days, indicating that spore survival is possible in a humid environment at ambient temperatures.^{23,50}

76 CHAPTER 76 Cytauxzoonosis

Craig E. Greene

James Meinkoth

A. Alan Kocan[†]

76.1 ETIOLOGY AND EPIDEMIOLOGY

Cytauxzoon felis causes a tick borne blood protozoal disease of domestic cats (*Felis domesticus*) and exotic Felidae from several central, south central, and southeastern states in the United States (Fig. 76-1). This distribution corresponds somewhat with the only known tick vector, *Dermacentor variabilis*. Infection of domestic cats results in a rapidly progressive, usually fatal, disease. The natural reservoir host appears to be the North American bobcat (*Lynx rufus*), in which infection is usually exhibited as a persistent, but asymptomatic, erythroparasitemia. Other wild cats may also harbor the organism. In a study of naturally exposed exotic cats in Florida, the prevalence of asymptomatic infection for transplanted Texas cougars was 39% and for Florida panthers was 35%.³⁰ Fatal cytauxzoonosis was reported in a captive reared white tiger (*Panthera tigris*) at a private breeding facility in northern Florida.¹⁰ Florida panthers (*Puma concolor coryi*) and a Texas cougar (*P. concolor stanleyana*) at this facility were also suspected of being infected. In Germany, a captive Bengal tiger (*Panthera tigris*) developed fatal cytauxzoonosis, presumably after contact with bobcats imported from North America.¹⁶ The organism has previously been recognized in the erythrocytes of cheetahs (*Acinonyx jubatus*).³³ Iatrogenic transmission from a Florida panther to a domestic cat has been reported.⁴ Cytauxzoonosis, caused by similar organisms as evaluated by light microscopy, was first described in African ungulates. Electron microscopic examination of a natural, fatal case of African cytauxzoonosis in a tsessebe calf (*Damaliscus lunatus*) showed the size and appearance similar to those described for *C. felis*.¹⁷ Organisms genetically similar to *C. felis* have been identified in cats in Spain,⁶ South Africa,¹ and in a Pallas' cat (*Otocolobus manul*) from Mongolia.¹⁸ Therefore this disease may be more widespread than was previously recognized. Reservoir hosts and vectors will need to be determined for these newly recognized foci of infection.

Cytauxzoon has been classified in the order Piroplasmida and family Theileriidae. This family has both an erythrocytic and a leukocytic, or tissue, phase. In the case of *C. felis*, the tissue phase consists of large schizonts that develop within macrophages, whereas *Theileria*, a more familiar genus of this family, has its exoerythrocytic phase primarily within lymphocytes. The Babesiidae, a related family, is characterized by having only or primarily an erythrocytic (piriform) phase in the mammalian host that is indistinguishable from the erythrocytic form in *Cytauxzoon*. Although no serologic cross reactivity has been reported between *C. felis* and the South African parasites *Theileria taurotragi* and *Babesia felis*, RNA gene sequence analysis links *C. felis*, *Babesia equi*, and *Babesia rodhaini* to both the theilerias and babesias, with some suggestion that these three organisms be reclassified within a separate family.^{1,7}

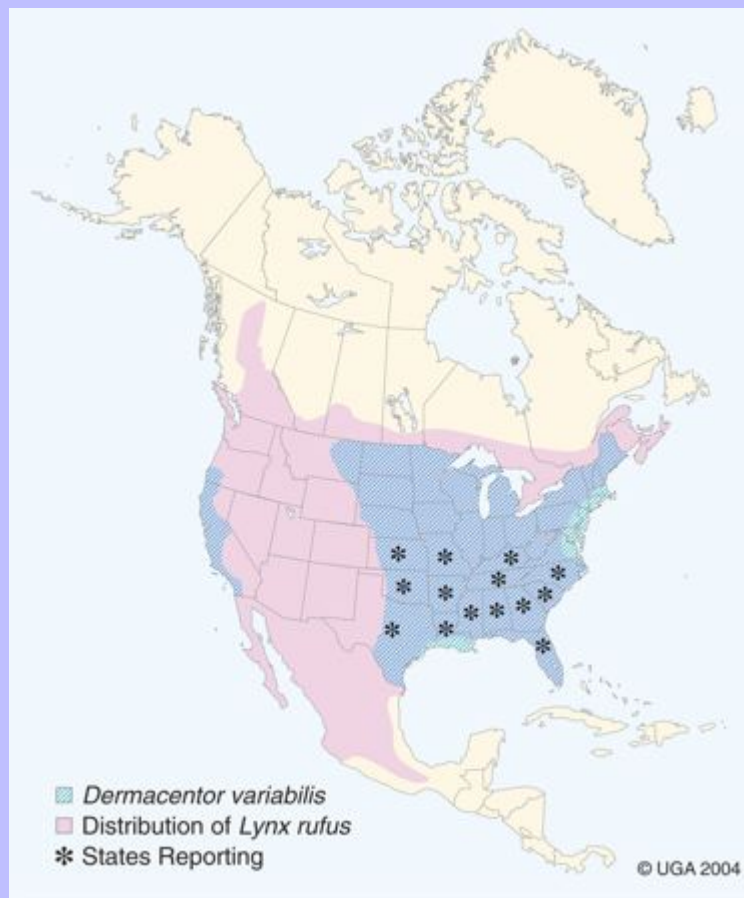

In the life cycle of *C. felis*, schizonts develop primarily within mononuclear phagocytes, first as indistinct vesicular structures within the cytoplasm of infected cells and later as large, distinct, nucleated schizonts that actively undergo division by schizogony and binary fission (Fig. 76-2).²² The phagocytes line the lumens of vessels within almost every organ and become huge and numerous, often occluding the vessel similar to a thrombus. Multiplication of schizonts within host cells is observed ultrastructurally to be true schizogony, without

Infectious Diseases of the Dog and Cat, 3rd Edition

host cell division. Later in the course of the disease, schizonts develop buds (merozoites) that separate and eventually fill the entire host cell. The host cell probably ruptures, releasing the merozoites into the blood or tissue fluid. Merozoites appear in macrophages 1 to 3 days before they are observed in erythrocytes. These organisms then invade uninfected erythrocytes and produce late stage parasitemias that are detected on examination of blood films, usually 1 to 3 days before death.²⁰

717

Fig 76-1 Map of distribution by state of reported cytauxzoonosis in the United States, along with overlapping distribution of the tick and reservoir host. (Courtesy University of Georgia, Athens, Ga.)

The apparently sporadic occurrence, short course of illness, and usually fatal nature of the disease indicate that the domestic cat is likely an incidental dead end host. However, at least two cats with naturally occurring infections and two experimentally inoculated, untreated cats have survived.^{13,28,32} In contrast, the schizogenous phase is limited and transient in infected bobcats that usually develop a nonfatal erythrocytopenia and serve as potential carriers.³ Infection rates as high as 60% in clinically healthy, wild-trapped bobcats has been reported.¹² However, fatal disease has been reported sporadically in some bobcats.^{3,21,29}

Infectious Diseases of the Dog and Cat, 3rd Edition

Ticks likely are the natural vector for *Cytauxzoon* because most cases have been associated with the presence of ticks on the hosts. Tick (*Dermacentor variabilis*) transmission from wild caught, splenectomized bobcats with parasitemia to two splenectomized domestic cats resulted in the fatal form of the disease. Conversely, subinoculation of blood from bobcats to cats appeared to transmit only the erythrocytic piroplasm stage resulting in asymptomatic parasitemia.² The fatal form of the disease with extraerythrocytic stages develops only, or primarily, after tick transmission of the organism or inoculation of schizont-containing tissues from fatally infected cats. In the white tiger that developed naturally occurring fatal disease in Florida, two female Lone Star ticks (*Amblyomma americanum*) were present on the inguinal skin.¹⁰

† Deceased.

76.2 PATHOGENESIS

The prepatent period of natural infection is between 2 to 3 weeks. Rapid, intravascular multiplication of the tissue phase of the parasite is responsible for the severe clinical illness seen in domestic cats, most likely the result of mechanical obstruction of blood flow, especially through the lungs. By-products of tissue parasites may be toxic, pyrogenic, and vasoactive. The blood phase may induce destruction and phagocytosis of erythrocytes, although erythroparasitemia in the absence of schizogenous development is of little clinical significance. Disseminated intravascular coagulation (DIC) has been a complication based on laboratory findings in naturally infected cats.^{10,13} Infected cats appear to die from a shocklike state.

76.3 CLINICAL FINDINGS

In the naturally occurring disease, affected cats develop nonspecific clinical signs that lead to a rapid course of illness and death, usually in fewer than 5 days. Most cats are presented from March through September, and geographic clusters of infection may be observed. Access to an outdoor, wooded environment or tick exposure is typically noted. Anorexia, dyspnea, lethargy, dark urine, dehydration, depression, icterus and pallor, anemic heart murmur, capillary refill time greater than 2 seconds, and fever (39.4° to 41.6° C [103° to 107° F]) have been observed (Fig. 76-3). Some cats vocalize as if in pain. Hypothermia, recumbency, and coma are clinical findings in terminally ill cats.

Clinical signs in experimentally induced cytauxzoonosis have been similar to those in naturally occurring cases. Incubation periods have varied from 5 to 20 days, probably attributable to type and dose of inoculum, method of cryopreservation, and individual cat response. After a febrile period (39.9° to 40.1° C [103.8° to 104.2° F]), the temperature may become subnormal, and the cat may have difficulty breathing. Parasitized erythrocytes are observed late in the disease, during the febrile episode. Cats usually die 2 or 3 days after the temperature peak, and the entire course of clinical illness usually takes less than a week.

76.4 DIAGNOSIS

Cytauxzoonosis should be considered in the differential diagnosis when a cat that is allowed access to tick infested, wooded areas becomes depressed and develops high temperature and possibly anemia and jaundice. Confusion with hemotropic mycoplasmosis (formerly haemobartonellosis) is most frequent (see Chapter 31). Generally, cytauxzoonosis can be suspected when anemia is mild relative to the degree of icterus. Instead of the strongly regenerative anemia typical of hemolysis, the anemia of cytauxzoonosis is normocytic, normochromic, and nonregenerative. The leukocyte count may be variable, but a profound leukopenia or thrombocytopenia, or both, are present, particularly late in the course of disease. High serum concentrations of total bilirubin and

Infectious Diseases of the Dog and Cat, 3rd Edition

bilirubinuria are common findings. Other clinical chemistry changes are variable and less specific but include low serum concentrations of albumin, cholesterol, and potassium and high serum glucose and alanine aminotransferase activity.¹⁵ Although serum urea nitrogen and ammonia concentrations and hepatic enzyme activities may be elevated in febrile or comatose animals, they may not be elevated earlier in the course of disease. Along with thrombocytopenia, prolonged activated coagulation, activated partial thromboplastin time (APTT), and prothrombin time tests and increased fibrin split products will be present in cats with DIC.^{10,13,14} Cats with cytauxzoonosis do not always have prolongation of all coagulation values; the APTT, in conjunction with thrombocytopenia, is usually most consistently elevated.

717

Fig 76-2 Life cycle of *C. felis*. **A**, Free merozoites, released from schizonts, **(B)** enter circulating erythrocytes by endocytosis and **(C)** undergo replication in a variety of forms. The circulating parasitized erythrocytes are ingested by the tick and **(D)** are released into the gut. **E**, These differentiate into macro- and micro-gamonts which unite to form a zygote. This differentiates into an ookinete which replicates by asexual reproduction and finally penetrates the gut wall and migrates to the salivary gland. **F**, Once there, asexual reproduction by merogony results in salivary infection, **(G)** via budding of organisms from the cell surface. **H**, During feeding, the organism is inoculated by the tick and enters mononuclear phagocytes. **I**, Within the phagocytes, replication by schizogony and binary fission leads to large parasitized cells that often occlude the blood vessel lumen. Merozoites engorge the cell until it ruptures releasing the merozoites into the blood and the cycle continues (Courtesy University of Georgia, Athens, Ga.)

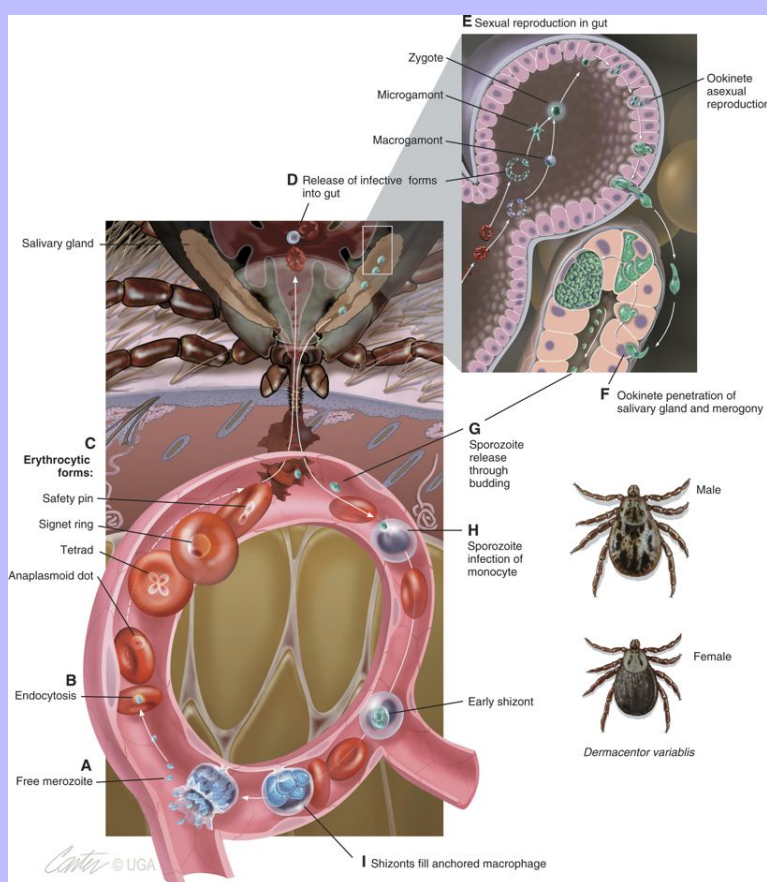

Fig 76-3 **A**, Cat showing paleness from *Cytauxzoon* infection. **B**, Serum (glass tube, top left) and urine (syringe, bottom right) show high bilirubin content. (Courtesy University of Georgia, Athens, Ga.)

Definitive diagnosis is most commonly made by demonstrating the erythrocyte phase (piroplasms) in Wright's or Giemsa stained thin blood films. The piroplasms within erythrocytes appear as round "signet ring"-shaped bodies, 1 to 1.5 μm in diameter; bipolar oval "safety pin" forms, $1 \times 2 \mu\text{m}$; tetrad forms; or anaplasmod round "dots," less than 0.5 μm in diameter (Fig. 76-4). All forms may occur in a single blood film, the signet ring-shaped organisms being most characteristic. A single cell usually contains only one parasite, but pairs and tetrads (Maltese crosses) are observed occasionally. The nucleus of the piroplasm is round to elongated and stains purple to dark red. The cytoplasm stains light blue or may appear as an indistinct clearing of the erythrocyte adjacent to the nucleus. The erythrocytic stage of *Cytauxzoon* may appear similar to other hemoparasites. The prominent, well-defined nuclear area of *C. felis* piroplasms allows differentiation from the ring form of hemotrophic mycoplasmas. Piroplasms of some small *Babesia* spp., such as *B. felis*, and *Theileria* spp. are morphologically indistinguishable from those of *C. felis*. However, these organisms have not yet been reported to infect domestic cats in the United States.

The number of parasitized cells varies from cat to cat and with the stage of the disease, increasing as the disease progresses. The development of schizogenous tissue phases, which is responsible for clinical signs of disease, precedes the appearance of piroplasms in the peripheral blood by a few days. Therefore some cats examined early in the course of disease may not be parasitemic on initial evaluation. The number of parasites in peripheral blood smears may increase dramatically in a 24-hour period; therefore reevaluation may be helpful when cytauxzoonosis is suspected despite a negative blood smear. When quantitated, the percentage of parasitized erythrocytes during illness ranges from 0.5% to 4%. In terminally ill, moribund cats, parasitemia has been higher. The number of nucleated erythrocytes and erythrocytes with Howell-Jolly bodies may increase slightly.

If the parasitemia is absent or low, the schizogenous tissue phase may be found in Wright's or Giemsa stained aspirates or impression smears of spleen, lung, liver, bone marrow, or lymph node.⁹ Phagocytes containing tissue-phase schizonts are sometimes found on the feathered edge of a peripheral blood smear. Schizonts are first recognized as basophilic areas within the cytoplasm of macrophages (Fig. 76-5). As the developing schizont enlarges to fill the cytoplasm of the macrophage completely, the parasitized host cell enlarges greatly and develops a large, prominent nucleolus (Fig. 76-6). As the schizont matures, the purple nuclei of developing merozoites can be seen within the basophilic schizont (Fig. 76-7).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 76-4 Feline erythrocytes infected with characteristic, signet ring-shaped *Cytauxzoon* piroplasms. The large, clearly evident nuclear area allows the organisms to be differentiated from hemotrophic *Mycoplasma* organisms (Wright-Giemsa, ×330).

Thoracic radiographs may show a bronchointerstitial pulmonary pattern, presumably related to the schizogony occurring in the pulmonary tissues.²⁵ Endotracheal washings from one cat had a mixed cell pattern of macrophages, eosinophils, neutrophils, and lymphocytes, in decreasing order. Intracellular schizonts were observed in pulmonary macrophages.

In cats that die, histologic confirmation should be made from standard formalin fixed tissues (lung, lymph node, spleen, liver, heart, brain) sent to a veterinary pathology laboratory for parasite evaluation because hemotrophic mycoplasmosis and babesiosis do not have a tissue stage. A direct fluorescent antibody test for the detection of the tissue phase³¹ and a microfluorometric immunoassay system for the detection of the serum antibody to *C. felis*⁵ have been developed; however, neither test is commercially available. Polymerase chain reaction (PCR) has been used to document and follow infection in cats that survived infection, and it may become commercially available.^{27,1a} In one treated cat, the PCR results were positive 18 months after treatment,¹ although no organisms were detected on blood smear examination.²⁷ Because of the usually rapidly progressive nature of the disease, such tests are not needed in most routine cases.

719

720

Fig 76-5 Impression smear from a feline liver showing a macrophage contains a developing *Cytauxzoon* schizont. The early schizont (*outlined by arrowheads*) appears as a lobulated basophilic area within the cytoplasm of the host cell. A large, prominent nucleolus is present in the host cell nucleus (*long arrow*) (Wright-Giemsa, $\times 165$).

Fig 76-6 Two schizont-containing macrophages in an impression smear of feline spleen. The host cells are greatly enlarged as can be seen by comparison with the numerous small lymphocytes and plasma cells (*arrows*) in the background (Wright-Giemsa, $\times 66$.)

Infectious Diseases of the Dog and Cat, 3rd Edition

76.5 PATHOLOGIC FINDINGS

Gross findings in domestic cats include dehydration; pallor; icterus; hydropericardium; hydrothorax; enlarged, edematous, and hemorrhagic lymph nodes; accentuated hepatic lobular pattern; intraabdominal venous distention; splenomegaly; and petechial and ecchymotic hemorrhages on the serosal surfaces of abdominal organs and lungs (Fig. 76-8). The lungs are frequently congested and edematous, often with petechiae throughout (Fig. 76-9).

The characteristic lesion on histologic examination of feline cytauxzoonosis is the accumulation of a large number of parasitized mononuclear phagocytes containing schizonts in various stages of development. These cells are particularly prevalent within the lumens of veins of the lungs, liver, lymph nodes, and spleen, making these vessels appear partially or completely occluded (Fig. 76-10). Minimal inflammatory reaction is present in affected tissues. Spleen and lymph node should be used for tissue impression films, which should be stained with Wright's or Giemsa stain.

Fig 76-7 Higher magnification of cell in Fig. 76-6. The host nucleus (*outlined by arrowheads*) with an enlarged nucleolus is visible. The developed schizont completely fills the cytoplasm and the nuclear material of the developing merozoites is evident (*small arrows*) (Wright-Giemsa, $\times 330$).

76.6 THERAPY

Preliminary attempts to treat cats that have either naturally or experimentally induced disease have had very limited success. The domestic cat as an unnatural host appears highly susceptible to this organism. Some evidence for more recent adaptation exists in that cats are being presented for clinical illness rather than at postmortem.^{13,27} Strains from different geographic areas may also vary in virulence. Since 1997, an increasing number of cats from a limited geographic area in northwestern Arkansas and northeastern Oklahoma have survived natural infection, most without receiving any specific, potentially effective antiprotozoal treatment.²⁷ These cats appear to be immune to subsequent challenge with virulent *C. felis*.²⁶ In most other reports, even with the most effective drugs,

Infectious Diseases of the Dog and Cat, 3rd Edition

the mortality is extremely high. Of the recovered cats, supportive care is essential. Supportive diuresis with isotonic intravenous fluids and adjunctive heparin is necessary to control concomitant DIC.¹⁴

Parvaquone, sodium thiacetarsemide, buparvaquone, and tetracycline appear to be ineffective. One cat treated with fluids, enrofloxacin, and tetracycline survived, although therapy was likely not related to survival in this animal.³² This cat came from the area in northeastern Oklahoma in which survivors have subsequently been commonly reported and may in fact represent an early infection with a less virulent strain. Most success in treatment has been with the carbanilide compounds, diminazene, or imidocarb. Imidocarb is commercially available in the United States (see Drug Formulary, [Appendix 8](#)).¹⁴ The drug is given as two injections within a 1- to 2-week interval. Parasympatholytic drugs such as atropine or glycopyrrolate should be given before treatment to counteract potential parasympathetic side effects. Morphologic examination of the organisms in blood smears showed a degenerating appearance within 48 hours after drug therapy was instituted. Enrofloxacin has also been used in a limited number of cats, in combination with the carbanilides; however, its efficacy has not been substantiated. Recommended dosages for these drugs are listed in [Table 76-1](#). Within the first week following treatment, the cat develops a hemolytic anemia, presumably as a result of destruction of dying organisms in infected erythrocytes. Cats that recover subsequently have an increase in their erythrocyte neutrophil and platelet counts. Blood transfusions may be required in cats that have the most severe hemolytic anemia following treatment.

720

721

Fig 76-8 Gross lesions in a cat experimentally infected with *C. felis* include a greatly enlarged spleen and a slightly enlarged liver with rounded edges and distended veins.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 76-9 Petechial and ecchymotic hemorrhages throughout the lungs of a cat that died from cytauxzoonosis. (Courtesy Oklahoma State University Veterinary Pathobiology Teaching Set, Stillwater, Okla.)

Table 76-1 Therapy for Cytauxzoonosis

DRUG ^a	DOSE ^b	ROUTE	INTERVAL	DURATION (DAYS)
Heparin	100–150 U/kg	SC	8 hours	As needed
Atropine	0.04 mg/kg	IV, IM, SC	24 hours	1 ^c
Glycopyrrolate	0.005–0.01 mg/kg	IV, IM, SC	24 hours	1 ^c
Enrofloxacin ^d	5.0 mg/kg	PO, SC	12 hours	7–10
Imidocarb dipropionate	5.0 mg/kg	IM	14 days	14
Diminazene aceturate	2.0 mg/kg	IM	7 days	7

SC, Subcutaneous; IV, intravenous; IM, intramuscular; PO, by mouth.

- a See Drug Formulary, [Appendix 8](#), for specific information on each drug. Adjunctive isotonic fluid therapy is extremely important for this disease. See text.
- b Dose per administration at specified interval.
- c Given once, 15 minutes before injection of imidocarb or diminazene.
- d The efficacy of this drug alone for cytauxzoonosis is uncertain. Use of imidocarb or diminazene is recommended instead or in combination. Higher dosages of enrofloxacin previously used have been associated with retino toxicity.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 76-10 Section of lung from a cat with cytauxzoonosis. Schizont-containing macrophages completely line the endothelial surface and nearly occlude the lumen of a large vessel. The enlarged nucleoli of host cell nuclei are visible in some cells (*arrowheads*). Developing organisms can be seen as a faint granular appearance to the cytoplasm of some of the cells (*arrow*) (H and E stain, $\times 66$).

76.7 PREVENTION

A conscientiously applied ectoparasite control program and confinement indoors during tick season may be beneficial in preventing cytauxzoonosis because all naturally occurring cases have involved cats that were free to roam in wooded, tick infested areas. See [Chapter 94](#) for more extensive information on tick control.

77 CHAPTER 77 Babesiosis

Joseph Taboada

Remo Lobetti

Canine babesiosis (piroplasmosis) is an important worldwide, tickborne disease caused by hemoprotezoan parasites of the genus *Babesia*.^{82,138,141} *Babesia* organisms primarily cause erythrocyte destruction, and the severity of illness can range from a relatively mild to a fatal disease. Although hemolytic anemia is the hallmark of infection, numerous variations exist and complications involving multiple organs may develop.

77.1 ETIOLOGY

Babesia canis and *Babesia gibsoni* have been the two predominant species capable of naturally infecting a dog. Strains of these organisms are found worldwide (Table 77-1). A small *Babesia* organism resembling *B. gibsoni* has been described and may be a third species affecting dogs in California.^{32,75} In Spain an organism resembling *Babesia microti* and tentatively being described as *Theileria annae* has been described in dogs.^{172,173} *Babesia equi* has been isolated from dogs in Spain.³³ In cats, *Babesia felis*, *Babesia cati*, *Babesia herpailuri*, *Babesia leo*, and *Babesia pantherae* have been reported (see Table 77-1).^{82,141}

77.1.1 Dogs

B. canis is a large (2.4 $\mu\text{m} \times 5 \mu\text{m}$), piriform-shape organism that exists singly or paired within erythrocytes (Fig. 77-1, A). Its expansive geographic range includes most of southern Europe, Africa, Asia, North America, Central America, and South America. Based on genetic, serologic, and cross-immunity studies, as well as differences in pathogenicity and vectors, a trinomial nomenclature system for *B. canis* has been proposed.^{26,149,174} *B. canis vogeli* is the proposed name for the strain that is found in tropical and subtropical regions of most continents and transmitted by the brown dog tick *Rhipicephalus sanguineus*. It is the least pathogenic of the three strains and is the one found in the United States. *B. canis canis* is the name proposed for the strain in Europe and parts of Asia. It is intermediately pathogenic and transmitted by ticks of the *Dermacentor* genus. *B. canis rossi* is the proposed name for the highly pathogenic strain that is found in South Africa and transmitted by *Heamaphysalis leachi*. A large strain, a yet unclassified *Babesia*, was isolated from a dog with hemolytic anemia, leukopenia, and thrombocytopenia.^{14a}

B. gibsoni is a small, pleomorphic (1 $\mu\text{m} \times 3.2 \mu\text{m}$) organism usually observed singly within erythrocytes (see Fig. 77-1, B). Initially, it was found primarily in northern Africa and the southern parts of Asia but has now been found in Australia, Europe, and the United States.

Other small *Babesia* species have been isolated from clinically ill dogs. The organisms were likely acquired from ticks that fed on infected wildlife reservoirs. In the western United States an unnamed species similar to the CA1 strain that infects people in the region causes hemolytic anemia in dogs.⁷⁵ Another unnamed species closely related to *B. microti* or *Theileria*, tentatively named *Theileria annae*, was found in the Pyrenean region of Spain.¹⁷² A Spanish isolate of *B. equi* was identified in a dog.³³

Infectious Diseases of the Dog and Cat, 3rd Edition

77.1.2 Cats

Feline babesiosis has not been studied as extensively as the canine form. *B. felis* is a small, highly pathogenic strain that infects domestic cats in southern Africa and the Sudan. Infection of domestic cats primarily has been identified in the strip along the coast of South Africa.^{68,119} The other small strain, *B. cati*, is less pathogenic and found primarily in India. Genetic sequences of *B. canis canis* have been amplified from the blood of three cats from Spain and Portugal³⁴; however, no organisms were visualized. *B. canis* ssp. *presentii* was identified in two cats in Israel.⁹ The ill cat was coinfecting with feline immunodeficiency virus (FIV) and *Mycoplasma haemominitum*. No cases of feline babesiosis have been reported in the United States. *B. herpailuri* and *B. pantherae* are large *Babesia* organisms of wild Felidae in Africa and have been transmitted experimentally to the domestic cat.⁸² A small piroplasm (*B. leo*) similar to but serologically distinct from *B. felis* was isolated from lions (*Panthera leo*) in Kruger National Park.⁹²

77.2 EPIDEMIOLOGY

B. canis and *B. gibsoni* are the two species that cause canine babesiosis worldwide (see [Table 77-1](#)). *B. canis canis* is transmitted by *Dermacentor reticulatus* in Europe, and *B. canis vogeli* is transmitted by *R. sanguineus* in many temperate and tropical countries. *B. canis rossi* is transmitted by *H. leachi* in South Africa. Experimentally, *B. canis* isolates have been transmitted by *Dermacentor andersoni* and *Hyalomma marginatum*.^{40,82} In the United States, canine babesiosis caused by *B. canis vogeli* is most common along the Gulf Coast and in the southern, central, and southwestern states. Reported prevalence has ranged from 3.8% to 59%.¹⁴⁰ The seroprevalence is higher in adult dogs than in dogs younger than 1 year.¹⁵ In a serosurvey of dogs in Florida, 46% of 393 greyhounds were seropositive. The prevalence within kennels ranged from 17% to 100%; the lower prevalence was noted in kennels with more intensive tick control. None of 50 adult pet dogs that were not greyhounds surveyed were seropositive, implicating both environment and breed susceptibility as factors in determining seroprevalence in endemic areas.¹⁴⁰ Outbreaks may occur and are often localized to a relatively small area or to a kennel. Veterinarians in one practice may see affected dogs often, whereas neighboring practices in the same area may not see any at all.¹³⁸ Transplacental transmission of *B. canis* infections is suspected but unproven.⁴⁷

725

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 77-1 Common *Babesia* Species, Vectors, and Distribution

SPECIES	GEOGRAPHIC DISTRIBUTION	TYPICAL MORPHOLOGIC CHARACTERISTICS	RECOGNIZED TICK VECTORS	CLINICAL FINDINGS
Canine				
<i>Babesia canis vogeli</i>	Africa, Asia, Central America, South America, North America, northern and central Europe, Australia, Europe, foci in Asia	Large (2.4–3 × 4–5 µm), single or paired piriform bodies	<i>Rhipicephalus sanguineus</i> , <i>Hyalomma plumbeum</i> (?)	Mild disease with inapparent clinical signs; more severe in young animals
<i>B. canis canis</i>	Europe, foci in Asia	Large (2.4–3 × 4–5 µm), single or paired piriform bodies	<i>Dermacentor reticulatus</i>	Transient parasitemia and organ congestion
<i>B. canis rossi</i>	South Africa	Large (2.4–3 × 4–5 µm), single or paired piriform bodies	<i>Haemaphysalis leachi</i>	Highly virulent hemolytic or immune disease
<i>Babesia</i> (large strain) ^{14a}	North Carolina	Large (2.5–5 µm)	Unknown	Hemolytic anemia, thrombocytopenia, leukopenia
<i>B. gibsoni</i> (many strain variants)	Asia, including Japan, Sri Lanka, Malaysia, and India; northern and eastern Africa; Australia; midwestern and eastern United States; southern Europe	Small (1–2 × 3–4 µm), usually single annular bodies (<i>signet rings</i>) ^b	<i>Haemaphysalis bispinosa</i> ? ^a <i>R. sanguineus</i> ? ^a	Hemolytic anemia or chronic subclinical infection with weight loss and debilitation
Small <i>Babesia</i> organisms	California	Small (1 × 2.5 µm), usually single; occasional <i>maltese crosses</i>	Unknown (suspect wildlife reservoir)	Hemolytic anemia
<i>B. microti</i> -like (<i>Theileria annae</i>) ^c	Northwestern Spain	Small (1 × 2.5 µm), usually single	<i>Ixodes hexagonus</i> ? (suspect wildlife reservoir)	Severe hemolytic anemia, some animals develop renal failure
<i>B. equi</i> (Spain isolate 1)	Spain	Small (1 × 2.5 µm) usually single	Unknown	Hemolytic anemia
Feline^d				
<i>B. felis</i>	Africa, southern Asia, Europe	Small (0.9 × 0.7 µm), single or paired annular bodies	Unknown	Hemolytic anemia with chronic course; seen in domestic cats in South Africa
<i>B. herpailuri</i>	Africa, South America?	Large (1 × 2.5 µm), single or paired annular bodies	Unknown	Isolated from jaguarundi (<i>Herpailurus yagurundi</i>) in South America
<i>B. cati</i>	Indian subcontinent	Small (1 × 1.5 µm), single or paired annular bodies	Unknown	Isolated from Indian wildcat (<i>Felis catus</i>)
<i>B. canis</i> ssp. <i>presentii</i>	Israel	Large (2.7 × 1.7 µm) round to oval or ring-shape	Unknown	Profound anemia and icterus or nonsymptomatic
Human^e				

Infectious Diseases of the Dog and Cat, 3rd Edition

<i>B. microti</i>	North America: northeastern United States and Great Lakes region; Europe	Small, pleomorphic bodies	North America: <i>I. scapularis</i> ; Europe: <i>I. trianguliceps</i> , <i>I. ricinus</i>	Hemolytic anemia, fever, chills, mild or subclinical anemia
<i>B. divergens</i>	Europe	Small, pleomorphic bodies	<i>I. ricinus</i>	Hemolytic anemia, more severe than <i>B. microti</i> , often in those that have had a splenectomy
<i>B. divergens</i> – like	North America: Washington state, Missouri (MO1), Kentucky	Small, pleomorphic bodies, high-level parasitemia	Unknown	Hemolytic anemia, more severe than <i>B. microti</i> , often in those that have had a splenectomy
<i>B. odocoilei</i> -like (EU1)	Austria, Italy	Small, pleomorphic bodies, occasional <i>maltese crosses</i>	Unknown	Fever, hemolytic anemia in those that have had a splenectomy
<i>B. gibsoni</i> -like (CA1–CA4)	North America: California	Ring forms and tetrads	<i>Dermacentor</i> ? (identical isolates from deer and bighorn sheep)	Hemolytic anemia—severe if immunosuppressed or have had a splenectomy
<i>B. gibsoni</i> -like, WA-1, CA5–CA6	North America: Washington state, California	Ring forms and tetrads	<i>Dermacentor</i> ? (only infects hamsters, not dogs) ¹⁴⁵	Hemolytic anemia
?, Association as a tick vector has not been proved but is suspected.				

- a Definitive studies identifying vectors for *B. gibsoni* have not been published; most evidence is circumstantial.
- b Some *B. gibsoni* isolates are larger and have a heterogenous appearance resembling *B. canis*, so PCR testing gives the most reliable differentiation.
- c *Theileria annae* has been proposed as a new name for this organism.^{23,172}
- d Also includes *B. pantherae*, which has been isolated from a leopard cat (*Panthera pardus*) in Kenya, and a small piroplasm that has been isolated from lions (*Panthera leo*) in the Kruger National Park, South Africa.⁹²
- e People are thought to be accidental hosts for babesias of reservoir animal hosts (e.g., *B. microti* [rodents], *B. divergens* [cattle]).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 77-1 Blood smears from dog with babesiosis. **A**, Pair of large, piriform-shape merozoites of *B. canis* within erythrocytes. **B**, Individual merozoites of *B. gibsoni* in erythrocytes (Wright stain, ×1000). (Courtesy Ken Latimer, University of Georgia, Athens, Ga.)

Infections with *B. gibsoni* occur throughout the world, and the insidious nature of this infection has allowed the inadvertent transport of the organism from Asia to other areas. Definitive proof identifying the vectors in this infection is lacking. In its original endemic area of Asia, the geographic range of *B. gibsoni* correlated with that of the suspected vector ticks, *Haemaphysalis bispinosa*, and *R. sanguineus*.⁸² *Haemaphysalis longicornis* and *H. leachi* were also incriminated in some areas. Most of the isolations have been from dogs in the eastern and midwestern regions of the United States. Transmission studies proving vector competence for both *R. sanguineus* and *Dermacentor variabilis*, both of which are found in the United States, have been unsuccessful or inconclusive.¹⁶⁷ Various stages of the parasite were found in the salivary glands of engorged *R. sanguineus*; however, infection could not be transovarially or transstadially transmitted to other dogs.¹⁶⁷

Infections with *B. gibsoni* occur sporadically in the United States, most often in American Staffordshire and American pit bull terriers or dogs that have been in fights with them.^{10,13,60,93} The identified strains are those likely imported from Asian countries. American pit bull terriers in Australia have also been found to have the imported infections,^{70,108} and isolated infections have been reported in Europe.¹⁵⁷ Although seroprevalence shows exposure to *B. gibsoni* to be highest in adult dogs, those younger than 1 year are most susceptible to clinical illness.⁶³ Because pups and many dogs within the same breed are infected, transmission from dam to offspring is suspected, although an exact mode of transmission is uncertain. Dogs younger than 2 months may be protected by maternal antibodies. Younger age is not a significant factor in the severity of clinical disease caused by *B. gibsoni*. In kennels where *B. gibsoni* infections have been problematic, nonvector transmission is suspected. The high prevalence of babesiosis among American pit bull terriers in many countries is likely a result of breed susceptibility and environmental factors that lead to extensive exposure to vector ticks.^{10,93} In addition, fighting

Infectious Diseases of the Dog and Cat, 3rd Edition

may play a role in transmission—through bite wounds and intermingling of blood, through saliva, or through ingested blood.^{10,98} Dogs who became infected after fighting with infected dogs developed clinical signs of illness within 2 weeks. Sharing instruments for surgery, such as those used for tail docking, and reusing needles for vaccinations can result in transmission of all *Babesia* species. However, transmission via fomites has not been documented in the previously mentioned kennels, so fighting is still considered the most likely mechanism of infection.

Small-strain (CA1) organisms reported in California infect various dog breeds in different housing situations, and older dogs have a greater prevalence of seropositivity.¹⁶⁶ The parasite most closely resembles *Babesia* isolated from mule deer (*Odocoileus hemionus*) and bighorn sheep (*Ovis canadensis nelsoni*) in the western United States.⁷⁵ It was also similar to the WA1-type strains, which have been isolated from people in the western United States.^{75,120,121} Babesial developmental stages have been detected in *R. sanguineus*; however, transmission has not been shown.¹⁶⁷

The previously mentioned Spanish isolate of *Babesia* (tentatively classified as *T. annae*) is closely related to *B. felis*, *B. microti*, and isolates from wild felids in Africa.^{75,92,172} Based on ticks collected from infected dogs, *Ixodes hexagonus* is the suspected principal vector.²⁵

The characteristic geographic ranges established for the various *Babesia* species is based on close vector relationships. Because of the international transport of dogs and cats, new infections may be reported any time they are identified in new areas. In addition, exposure of these infected animals to vectors in new regions may allow the infection to become established in new vectors and hosts. Furthermore, people and animals are becoming exposed to new pathogens as they settle and reproduce in new environments in which sylvatic cycles between vectors and their reservoir hosts exist. This has been apparent with the increasing number of new isolates of *Babesia* in people and animals.

Babesias are transmitted through the bite of infected ixodid ticks (Fig. 77-2). The adult female tick is most important in transmission, but with *B. canis*, all stages of the tick are likely to be infected.⁴⁰ Of the *Babesia* organisms that are not transmitted transovarially, larvae are not infected. Once in the host, *Babesia* species attach to the erythrocyte membrane and are engulfed by endocytosis.⁵⁸ Once in the erythrocyte, the red blood cell membrane that surrounds the parasite disintegrates, and all subsequent stages are in direct contact with the host cell cytoplasm. *B. canis* multiplies within the erythrocytes by repeated binary fission, creating merozoites. As many as 16 merozoites of *B. canis* may be seen in a single erythrocyte, but they most commonly exist singly or in pairs. Ticks are infected by ingesting merozoites during feeding. A complex life cycle involving transtadial and transovarial transmission results in sporozoite formation in cells of the tick's salivary glands.^{40,58} When infected ticks feed, the sporozoites are passed with saliva into the circulation of the host. The tick must feed a minimum of 2 to 3 days for transmission of *B. canis* to occur.⁹⁶

Several differences in life cycles have been identified in non-*B. canis* infections. Transovarial transmission in ticks is not a feature of *B. gibsoni* infections. Furthermore, the California strain of *Babesia* replicates into tetrads or Maltese crosses and does not undergo binary fission.

77.3 PATHOGENESIS

The pathogenic sequence of events in babesiosis is summarized in Fig. 77-3. After infection, a significant host immune response usually is generated. The immune system does not appear able to completely eliminate the

Infectious Diseases of the Dog and Cat, 3rd Edition

infection, and animals that recover are usually chronic carriers of the parasite. Poor humoral immune response is common in pups younger than 8 months. Transplacental transmission of *B. canis* is likely and may result in weak or fading puppies.^{20,47,139} In one instance, *B. canis* infection was diagnosed in a 36-hour-old greyhound pup that was born to a seropositive bitch. The pup's hematocrit (HCT) was lower than the levels of its four littermates.¹³⁹

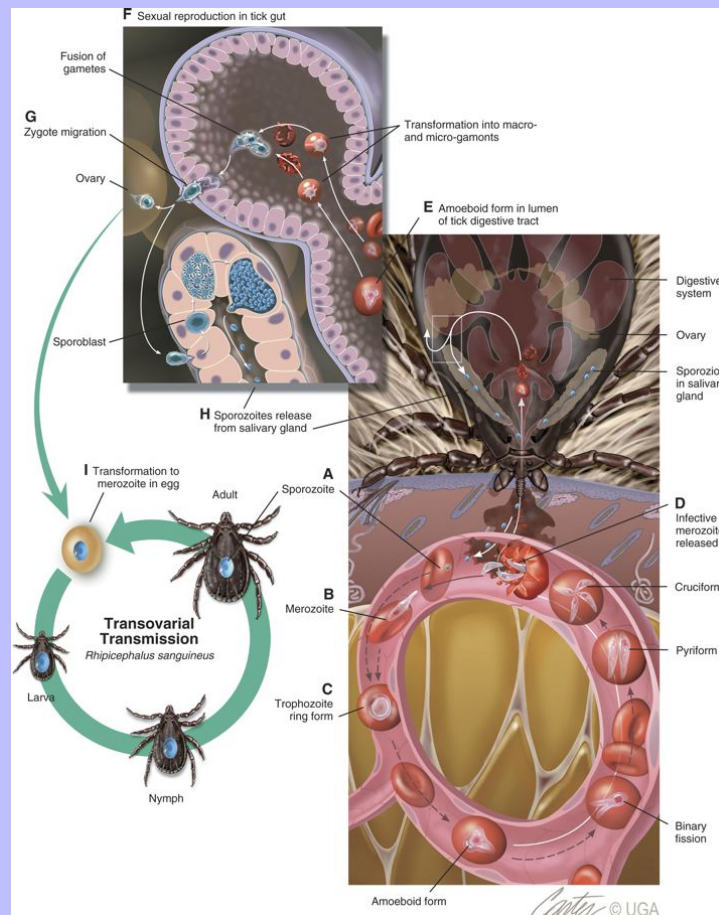

The pathogenicity of *Babesia* organisms is determined primarily by the species and strain involved.^{125,149,163} Host factors, such as the age of the host and the immunologic response generated against the parasite or vector tick, are also important.¹⁵¹ Infected erythrocytes incorporate parasite antigens into their surface and induce antibodies in the host that opsonize the erythrocytes, which leads to removal of infected erythrocytes by the mononuclear-phagocyte system. Splenectomy makes the anemia and parasitemia more severe.²⁴

725

727

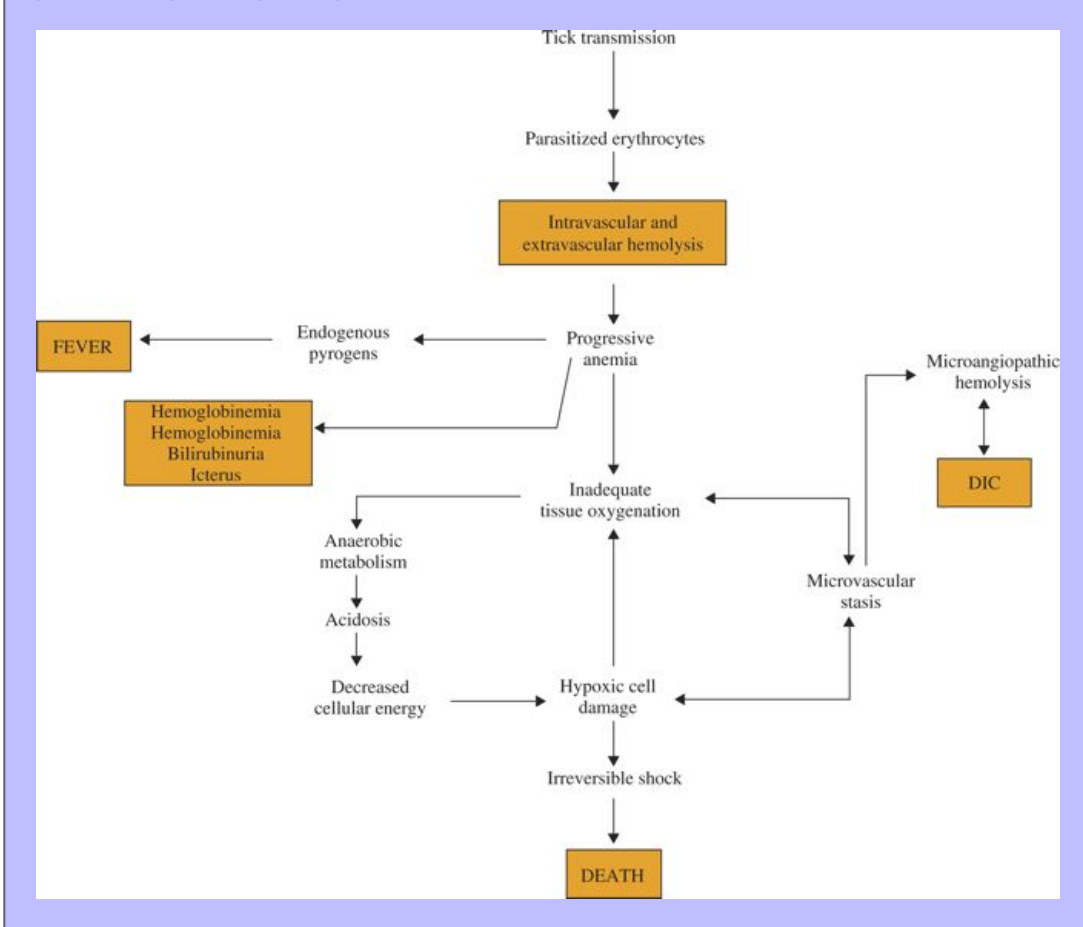

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 77-2 Life cycle of *B. canis*. **A**, Sporozoites of the organism enter the blood following tick feeding, and infect erythrocytes by focal host erythrocyte membrane invagination and dissolution. **B**, The organisms differentiate into merozoites, and then **(C)** pleomorphic trophozoites (forms). These divide within erythrocytes by binary fission causing eventual cell lysis. The asexual reproduction (merogony) also produces more merozoites **(D)** which infect new erythrocytes. If infected erythrocytes are ingested by ticks **(E)**, organisms appear in the tick gut about 10 hours after feeding. **F**, They differentiate into gametes which penetrate the tick gut epithelium fuse to form a zygote. **G**, The zygote penetrates the gut, enters the hemolymph, and migrates to the salivary gland tissue. **H**, Sporozoite replication occurs within the salivary gland and cells become filled and they eventually bud from the surface epithelium into the tick's saliva. (Courtesy University of Georgia, Athens, Ga.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 77-3 Proposed pathogenesis of canine babesiosis.

Two syndromes, one characterized by hemolytic anemia and the other by multiple-organ dysfunction syndrome (MODS), account for most of the clinical signs observed in animals with babesiosis (see Fig. 77-2).^{62,63} MODS has primarily been associated with the most pathogenic *B. canis rossi* infections found in South Africa and often causes intravascular hemolysis. Parasitemia results in osmotically fragile erythrocytes, hemolysis, and subsequent anemia.⁹⁴ However, the severity of anemia is not proportional to the low degree of parasitemia usually observed. Direct parasitic damage contributes to the anemia. However, induction of serum hemolytic factors, increased erythrophagocytic activity of macrophages, and damage induced by the secondary immune system after formation of antierythrocyte membrane antibodies are also important to the pathogenesis.^{3-5,107,109,111,112} Serum from infected dogs inhibits erythrocyte 5'-nucleosidase, which can lead to the accumulation of cyclic nucleotides and may contribute to erythrocyte damage.⁵⁶ Oxidative stress is another possible cause of damage to erythrocytes that also results in increased susceptibility to phagocytosis.¹¹⁰ Increased production of superoxide has been demonstrated in erythrocytes infected with *B. gibsoni*, which may relate to oxidative damage from lipid peroxidation.¹¹⁴ Increased urinary methemoglobinemia levels have been found in dogs with naturally occurring *B. canis* infections.⁹⁰ Lipid peroxidation occurring during *Babesia* infection increases rigidity of parasitized and nonparasitized erythrocytes and slows their passage through capillary beds. Soluble parasite proteases activate the

Infectious Diseases of the Dog and Cat, 3rd Edition

kallikrein system and induce fibrinogen-like protein (FLP) formation. The FLPs make erythrocytes more “sticky,” leading to additional erythrocytes sludging in the capillaries. Vascular stasis from sludging of parasitized cells and erythrocyte stroma within capillary beds is thought to contribute to the acute anemia and many of the other potential clinical signs. The most severe sludging appears to occur in the central nervous system (CNS) and muscles.¹⁶³ Rhabdomyolysis and acute renal failure have been complications of babesiosis.^{64,91}

Thrombocytopenia alone is observed in many cases of babesiosis and may relate to immune or coagulatory consumption of platelets from hemolytic or vascular injury. Abnormal coagulation results are not found in many dogs.⁴⁵ However, overt disseminated intravascular coagulation (DIC) can be a devastating complication of the severe forms of canine babesiosis caused by *B. canis rossi*. *Babesia* proteases may induce increases in plasma kallikrein levels, which can activate the intrinsic cascade at factor XII. Thrombocytopenia is common, especially in dogs infected with *B. gibsoni*. This condition can be a result of DIC but is also likely a result of immune-mediated platelet destruction. Membranoproliferative glomerulonephritis is seen in some infected dogs and may have an immune-mediated pathogenesis.

727

Tissue hypoxia is an important contributor to many of the clinical signs caused by the most pathogenic *Babesia* strains. Causes of hypoxia include anemia, shock, vascular stasis, excessive endogenous production of carbon monoxide, parasitic damage to hemoglobin, and decreased ability of hemoglobin to offload oxygen from *Babesia*-infected dogs.^{63,90} Hypoxia appears to be more important than hemoglobinuria in damaging the kidneys of experimentally infected dogs.⁹¹ Lactic acid generation from tissue hypoxia is considered the main reason for metabolic acidosis that develops in animals with babesiosis.⁸⁴ Respiratory alkalosis results partly from compensation but more directly from hyperventilation caused by hypoxemia.

728

Many atypical signs or complications can develop in animals with babesiosis, especially if caused by *B. canis rossi* infection; they cannot be directly explained by hemolysis but appear to be the result of the host inflammatory response. The resultant tissue damage probably causes the release of cytokines, which would be expected to support widespread inflammation and additional damage to multiple organs.⁶³ MODS complications resulting from the so-called *systemic inflammatory response syndrome (SIRS)* have been acute renal failure, hepatopathy, immune-mediated hemolysis, pulmonary edema, rhabdomyolysis, and cerebral dysfunction.¹⁶⁰ Pulmonary, CNS, and renal complications were associated with a higher rate of mortality.

77.4 CLINICAL FINDINGS

77.4.1 Dogs

77.4.1.1 General Features

Babesiosis may have a hyperacute, an acute, a chronic, or a subclinical course (Table 77-2). Acute disease characterized by fever and lethargy, and acute anemia is the most common clinical syndrome, whereas the hyperacute presentation characterized by extensive tissue damage is rare.^{32,38} *B. canis rossi*, prevalent in South Africa, is highly virulent and causes a hemolytic anemia or an acute overwhelming inflammatory response.¹²⁴ *B. canis canis* results in a low-level parasitemia (less than 1%), and clinical disease is associated with congestion of organs of the mononuclear phagocyte system.¹²⁷ *B. canis vogeli* results in mild clinical disease, generally without overt signs.

Infectious Diseases of the Dog and Cat, 3rd Edition

Acute clinical signs are typical of initial infections with *B. gibsoni* and the more virulent strains of *B. canis*.^{19,32} Acute disease is characterized by anorexia, hemolytic anemia, thrombocytopenia, lymphadenomegaly, and splenomegaly.^{2,61,63} Anorexia, lethargy, fever, and vomiting are also common. Fatalities may occur, especially in puppies and occasionally in *B. gibsoni*-infected adults, but most animals with this acute disease recover with treatment. Hematuria and icterus may be noted, especially in *B. canis*-infected dogs. The acute presentation is most typical of *B. gibsoni* infections encountered in Asia and the United States and *B. canis* infections encountered in Africa, Australia, and southern Europe. Immune-mediated hemolytic anemia (IMHA) and systemic lupus erythematosus are the primary diseases that must be differentiated from this form of babesiosis.

Chronic manifestations of *B. canis* infection are poorly characterized.⁶³ Most infected dogs with *B. canis vogeli* in the United States are subclinical carriers.¹⁴⁰ Low-grade or subclinical manifestations can also be seen with certain strains and more commonly with *B. gibsoni* infections.

77.4.1.2 Specific Clinical Features

77.4.1.2.1 *B. canis rossi* in South Africa

B. canis rossi is the most virulent form of canine babesiosis. Two general and severe manifestations have been described.¹²⁴ Clinical disease is often correlated with the degree of parasitemia.¹²⁷

Thrombocytopenia is a consistent finding in babesiosis and may be considered a screening test.⁷³ Severely anemic dogs had hypoxic hepatic disease and increased concentrations of serum urea without creatinine. Nonanemic dogs had severe azotemia and electrolyte disturbances. Hypoglycemia was a common finding in virulent canine babesiosis and was common in dogs with mental depression or other neurologic signs.⁷² As with *B. gibsoni* infections, fighting breeds such as bull terriers, American pit bull terriers, and Staffordshire bull terriers had a higher prevalence of *B. canis rossi* infections, with high mortality indicating increased susceptibility to or greater exposure risk of babesiosis.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 77-2 Clinical Findings in Dogs with Babesiosis¹³⁸

SPECTRUM	DURATION
Nonspecific Signs	Hyperacute Symptoms
Anorexia	Hypothermia
Lethargy	Shock
Weakness	Coma
Pyrexia	Disseminated intravascular coagulation
Weight loss	
Atypical Signs	Metabolic acidosis
Ascites	Death
Edema	Acute Symptoms
Constipation	Hemolytic anemia
Diarrhea	Icterus
Ulcerative stomatitis	Splenomegaly
Hemorrhage	Lymphadenopathy
Congested mucous membranes	Vomiting
	Chronic Symptoms
Polycythemia	Intermittent pyrexia
Ocular and nasal discharge	Partial anorexia
Respiratory distress	Loss of body condition
Masticatory myositis	Lymphadenopathy
Temporomandibular joint pain	
Back pain	
CNS signs	
Seizures	
Ataxia	
Paresis	

77.4.1.2.2

B. canis vogeli in greyhounds in the United States

The prevalence of babesiosis among greyhounds in the United States is high.¹⁴⁰ The likely organism affecting greyhounds is the Gulf Coast strain of *B. canis vogeli*, which rarely causes clinical disease in adults. No evidence suggests that these dogs are more susceptible than other breeds after experimental inoculation.³¹

77.4.1.2.3

B. gibsoni in Asia, Africa, Europe, the United States, and Australia

Typical clinical signs of *B. gibsoni* infection are intermittent fever, pale mucous membranes (Fig. 77-4), decreased appetite, and marked loss of body condition.²⁷ A low-grade or compensated hemolytic anemia and variable thrombocytopenia may be observed with laboratory testing. The chronic form of the disease has been frequently observed, especially in the United States. Dogs develop mild fever, pale mucous membranes, splenomegaly (Fig. 77-5), hepatomegaly, lymphadenomegaly, and lethargy without many of the complicating factors associated with other *Babesia* infections.¹⁰¹

728

729

Infectious Diseases of the Dog and Cat, 3rd Edition

77.4.1.2.4 California isolate

Clinical signs of dogs affected by the California *Babesia* isolate have included lethargy, vomiting, elevated rectal temperature, and pale mucous membranes caused by anemia.³² Most infected animals have developed acute severe hemolytic anemia and accompanying thrombocytopenia.

77.4.1.2.5 Spanish isolate

In Spain, disease caused by the *B. microti*-like agent (and being called *T. annae*) is associated with pale mucosae, weakness, hemoglobinuria, tachycardia, tachypnea, and elevated rectal temperature caused by regenerative hemolytic anemia and thrombocytopenia that in some cases was accompanied by renal failure.^{23,24,46,172} In animals with renal failure, nonregenerative anemia, azotemia, and proteinuria with high urine protein/creatinine ratios was found.²²

77.4.1.3 Uncomplicated Babesiosis

Canine babesiosis can be classified clinically as uncomplicated or complicated. The course and severity of the disease depends on the virulence of the infecting organism and the host's immunocompetency.

Coinfections with other organisms can create a confusing clinical illness and cause immunosuppression.¹⁴⁷

Animals with uncomplicated babesiosis typically have clinical signs relating to acute hemolysis, including fever, anorexia, depression, pale mucous membranes, splenomegaly, and water-hammer pulse. This form can be further classified as mild, moderate, or severe according to the severity of the anemia. Mild, uncomplicated babesiosis case can progress to become severe complicated babesiosis with life-threatening anemia.

77.4.1.4 Complicated Babesiosis

The clinical manifestations of complicated babesiosis are not easily explained by the hemolytic disease process. The development of many clinical or laboratory abnormalities often correlates with a greater degree of parasitemia. Rare complications include gastrointestinal (GI) disturbances, myalgia, ocular involvement, upper respiratory signs, cardiac involvement, necrosis of the extremities, fluid accumulation, and the chronic form of the disease. Overlap among the different categories of the complications can also occur.

Complications are most frequently reported in *B. canis rossi* infections in dogs from South Africa.

77.4.1.4.1 Acute renal failure

Acute renal failure (ARF) associated with babesiosis typically includes symptoms of anuria or oliguria despite adequate rehydration but is an uncommon complication. Evidence of renal damage, reflected on urinalysis by the presence of proteinuria, casts, and renal tubular epithelial cells, is common in complicated and uncomplicated cases but does not necessarily predict renal failure. An elevated serum urea alone is an unreliable indicator of renal insufficiency in animals with babesiosis, as a disproportionate rise in urea (compared with creatinine) has been related to catabolism of lysed erythrocytes.^{35a} Renal failure is diagnosed on the basis of ongoing evaluation of urine volume, urinalysis, and degree of azotemia.

Infectious Diseases of the Dog and Cat, 3rd Edition

Acute intrinsic renal impairment without overt ARF occurs in humans with malaria—a clinical picture very similar to canine babesiosis. Renal tubular epithelial and other cells in the urine sediment, enzymuria, proteinuria, and variable azotemia have been observed in dogs with *B. canis rossi* infections.⁹¹ ARF was also documented in numerous dogs in the same study.

77.4.1.4.2

Cerebral babesiosis

Cerebral babesiosis is defined as the concurrent presence of neurologic signs in an animal with babesiosis. The signs, typical of peracute onset, include a combination of incoordination, hind-quarter paresis, muscle tremors, nystagmus, anisocoria, intermittent loss of consciousness, seizures, stupor, coma, aggression, paddling, or vocalization.⁶³ Pathologic changes in the brain are congestion, macroscopic and microscopic hemorrhages, sequestration of parasitized erythrocytes in capillary beds, and paving of parasitized cells against the endothelium.

77.4.1.4.3

Coagulopathy

The most consistent hemostatic abnormality in babesiosis is profound thrombocytopenia, which is a routine finding in complicated and uncomplicated cases, but clinically apparent hemorrhages are relatively rare. DIC has been reported in animals with babesiosis; however, confirmation of DIC in animals with babesiosis is difficult because of the nature of the underlying disease process and the reported unreliability of the human fibrin degradation product test.⁶³ Clinical signs of DIC are difficult to recognize until hemorrhages develop in the hypocoagulable phase. In the hypercoagulable phase, signs are related to microthrombi-induced organ dysfunction.

729

77.4.1.4.4

Icterus and hepatopathy

In some cases of babesiosis, icterus, elevated liver enzyme levels, and elevated bile acid levels develop, which indicate a liver insult.¹⁰² Whether the insult is caused by inflammatory cytokines, hypoxic damage, or a combination of these is not known. Icterus does not solely appear to be caused by hemolysis or hepatic obstruction. Therefore liver dysfunction appears to be at least contributory. Histologic changes usually associated with icterus include diffuse and periportal lesions, whereas icteric dogs with babesiosis have a centrilobular lesion. However, it is possible that the liver has a diffuse, mild or moderate lesion that does not cause histologic changes but is severe enough to cause a functional change. Hypoxic insults are known to cause diffuse hepatocellular swelling, thus the hypoxia in severe babesiosis may be severe enough to cause a transient hepatopathy.

730

77.4.1.4.5

Immune-mediated hemolytic anemia

Immune-mediated hemolysis is an increased destruction of erythrocytes caused by erythrocyte-membrane-associated antibodies. This destruction can either be primary, in which the membrane is normal, or secondary, in which the membrane is altered and recognized as foreign. Secondary destruction is assumed to occur in babesiosis.¹⁴⁶ The cardinal feature of babesiosis-associated IMHA is continuing hemolysis despite successful antibabesial treatment. Diagnosis is confirmed by finding autoagglutination with saline dilution of blood, detection of spherocytosis, or both. The Coombs' test cannot be used to confirm a diagnosis because uncomplicated cases and cases complicated with IMHA have a positive test result.

Infectious Diseases of the Dog and Cat, 3rd Edition

77.4.1.4.6 Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is a severe and frequent catastrophic complication of babesiosis. Typical clinical signs are a sudden increase in respiratory rate (which may be caused by other factors, such as pyrexia and acidosis), dyspnea, moist cough, and blood-tinged frothy nasal discharge. The diagnosis of ARDS is based on the presence of diffuse pulmonary infiltrates on thoracic radiography, hypoxemia from ventilation-perfusion mismatch, normal pulmonary capillary wedge pressure, and reduced pulmonary compliance.³⁹ In most clinical situations, pulmonary wedge pressure, blood-gas analysis, and compliance cannot be measured. Thus diagnosis depends on the recognition of risk factors for ARDS, thoracic radiographs, and exclusion of other causes of pulmonary edema, particularly cardiogenic causes and fluid overload. Excluding fluid overload is particularly important in animals with oliguric renal failure. Fluid loads that can be tolerated by normal dogs may fatally exacerbate pulmonary edema in ARDS.

77.4.1.4.7 Hemoconcentration

The paradoxical phenomenon of severe intravascular hemolysis combined with hemoconcentration constitutes the syndrome “red biliary.” The clinical features are congested mucous membranes, visible hemoglobinemia, hemoglobinuria, or all of these and high-normal or elevated hematocrit levels.⁶³ Hemoconcentration has been associated with other complications, such as cerebral babesiosis, DIC, ARF, and ARDS. Hemoconcentration in babesiosis is thought to be a result of reduction in blood volume as a result of fluid shifts from the vascular to the extravascular compartment. Because plasma protein concentrations are normal, plasma—rather than a filtrate of plasma—shifts from the vasculature. The widespread increase in capillary permeability, which occurs in SIRS, may play an important role in the pathogenesis. Concurrent hypoalbuminemia may relate to a loss of albumin into the interstitium because of lost endothelial integrity associated with SIRS.

77.4.1.4.8 Hypotension

Dogs with severe and complicated babesiosis are frequently in a state of collapse and clinical shock. Shock can resemble the hyperdynamic phase of septic shock. In a study, it was shown that hypotension occurs frequently in dogs with babesiosis, and the presence and severity of hypotension increases with increased disease severity.⁶⁶ The presence of hypotension in a large proportion of dogs with complicated babesiosis is consistent with the hypothesis that inflammatory mechanisms play a major role in this disease and can result in a sepsislike state. It is likely that hypotension in animals with babesiosis is a combination of vasodilation, reduced vascular volume caused by increased vascular permeability, dehydration, or all of these and myocardial depression. Hypotension can play a role in the pathophysiologic symptoms of the disease because it has been hypothesized to facilitate parasite sequestration.

77.4.1.4.9 Cardiac changes

In one study, dogs with complicated and concurrent IMHA-babesiosis had significantly higher cardiac troponin I and T concentrations.⁸⁷ In this study, dogs with babesiosis developed important electrocardiogram (ECG) changes such as heart blocks, ventricular premature complexes (VPCs), and

Infectious Diseases of the Dog and Cat, 3rd Edition

prolonged QRS changes and ST segment changes. However, most of the changes were not associated with severity, outcome, and cardiac troponin levels. The exception was the presence of VPCs because a correlation was found between troponin concentrations and VPCs. Cardiac histologic changes reported in the study were hemorrhage, necrosis, inflammatory infiltrate, and fibrosis.

77.4.1.4.10 Acute pancreatitis

A retrospective study reported acute pancreatitis as a complication of canine babesiosis.¹⁰³ In this study, four dogs had histologic evidence of pancreatitis, and another 16 dogs had serum amylase elevations, lipase activity elevations, or both of a magnitude that supported a diagnosis of acute pancreatitis. The median time of pancreatitis diagnosis was 2.5 days postadmission, with primarily young (a median age 3 years), sexually intact dogs being affected. The development of pancreatitis was unrelated to the degree of anemia at time of admission. In addition to pancreatitis, 80% of dogs had other babesial complications, namely icterus, ARDS, IMHA, renal failure, hemoconcentration, and cerebral syndrome. Acute pancreatitis may represent the previously reported gut form of babesiosis.

77.4.1.4.11 Acid-base disturbances

Dogs with severe *B. canis rossi* infection have an arterial pH that varies from acidemia to alkalemia.⁸⁴ A high anion gap metabolic acidosis is present in many dogs, whereas almost all have concurrent metabolic acidosis and respiratory alkalosis. The severity of these abnormalities could not be linked to clinical outcome.

77.4.1.5 Subclinical Infections

Subclinically infected dogs are common in certain populations.^{98c} Greyhounds in the United States have a very high seroprevalence of disease, but adult dogs rarely show clinical signs. Likewise, American pit bull terriers appear to have a high prevalence of infection based on polymerase chain reaction (PCR) studies.⁹³ *B. canis* parasites are rarely found on blood smears from asymptomatic carriers, making identification of this group of dogs difficult without performing serologic screening tests or PCR. A slightly higher likelihood of finding *B. gibsoni* on blood smears from asymptomatic American pit bull terriers exists if the clinician examines the smears very thoroughly. However, serology and PCR are also more sensitive screening tools in this population of dogs. The primary importance of this group of dogs may be in their role as a potential source of infection to susceptible puppies in breeding colonies or as a source of infection through blood

730

transfusion or fighting.^{38,140} Babesiosis can be a significant and underdiagnosed cause of morbidity and mortality of puppies from breeding colonies located in endemic areas. The seroprevalence among adults in affected kennels often is higher than 75% and can serve as a serologic marker for the disease. In comparison, the seroprevalences are typically less than 20% in well-managed kennels from endemic areas where anemic puppies are less likely to be encountered.¹⁴⁰ Most subclinical carriers never show clinical signs of babesiosis; however, although rare, they may have symptoms when subjected to stress or treated with glucocorticoids.^{19,97}

731

77.4.2 Cats

The reports of clinical infection in domestic cats have been predominantly from South Africa. Cats with naturally occurring babesiosis usually are younger than 3 years and have no breed or sex predilection. Affected

Infectious Diseases of the Dog and Cat, 3rd Edition

cats generally have lethargy, anorexia, weakness, a rough hair coat, or diarrhea.⁶⁸ Fever and icterus are less common. Anemia can be severe and is the underlying reason for the clinical signs. The disease is chronic, and signs may not be apparent until a later stage of illness. Cats usually adapt to the anemia and may have only mild clinical signs until they experience the stress of a physical examination or diagnostic evaluation.¹⁰⁴ Complications of the hemolytic anemia included hepatopathy, pulmonary edema, renal failure, CNS signs, and concurrent infections.

77.5 DIAGNOSIS

77.5.1 Clinical Laboratory Findings

77.5.1.1 Dogs

The primary differential diagnoses for acute uncomplicated babesiosis are hemolytic states such as parasitic, immune-mediated, oxidative, and traumatic insults to erythrocytes and GI hemorrhage mimicking a hemolytic anemia. The clinical pathologic changes are nonspecific; the primary hematologic abnormalities are anemia and thrombocytopenia.^{2,61,99,113} The prevalence of thrombocytopenia is higher than that in dogs with ehrlichiosis. A mild, normocytic, normochromic anemia is generally noted in the first few days after infection, and the anemia then becomes macrocytic, hypochromic, and regenerative as the disease progresses. The reticulocytosis is proportional to the severity of the anemia. Uncommonly, a relative polycythemia with normal plasma protein concentration may be noted.⁶³ Leukocyte abnormalities are inconsistently observed but may include leukocytosis, neutrophilia, neutropenia, lymphocytosis, and eosinophilia.^{61,113} A leukemoid response similar to that in cases of IMHA is occasionally seen.⁸⁶ Autoagglutination of erythrocytes in saline was noted in 21% of 134 dogs with babesiosis in one study, and almost 85% of infected dogs were positive on direct antiglobulin (Coombs') test in another, making it difficult to differentiate the disease from IMHA if organisms are not apparent.⁶³ Thrombocytopenia is generally a feature of canine babesiosis, regardless of whether concurrent anemia is present.¹⁴⁷

Serum chemistry values are usually normal. Hypokalemia may be found in severely affected animals but is probably nonspecific because of decreased potassium intake. Hyperkalemia and hypoglycemia were noted in severely affected animals in one study.⁶¹ Dogs with mild and severe babesiosis have low total serum protein and albumin levels, albumin/globulin ratios, and α -globulin levels. They also have an acute-phase response characterized by elevated α 1-acid glycoproteins.⁸⁹ A study of dual infections with *B. canis* and *Ehrlichia canis* showed that the prevalence of hyperglobulinemia was higher in dogs with dual infections than in dogs infected with a single infection caused by either organism.⁹⁹ Azotemia and metabolic acidosis are common in animals with severe intravascular hemolysis and appear to contribute to morbidity and mortality. More severely affected animals have high serum transaminase and alkaline phosphatase activity and increased serum bilirubin levels. Hyperbilirubinemia is a consistent finding during acute disease caused by *B. canis* strains but not by *B. gibsoni*.^{61,156} Liver enzyme activity may be increased during severe disease. Urinalysis may reveal bilirubinuria, hemoglobinuria, proteinuria, and granular casts. In *B. canis rossi* infections in anemic South African dogs, animals can develop hypoxic hepatic disease with an increased serum urea and profound leukocytosis with a left shift.¹²⁴ Nonanemic dogs may have severe azotemia, marked electrolyte changes, and in some cases, leukopenia.

Infectious Diseases of the Dog and Cat, 3rd Edition

77.5.2 Cats

In feline babesiosis, which is caused by *B. felis*, the anemia is typically macrocytic, hypochromic, and regenerative.¹³⁰ No characteristic change in total or differential leukocyte counts occurs, and thrombocytopenia is an inconsistent finding. The in-saline agglutination test may also be positive.¹³⁰

Cats infected with *B. felis* typically have elevated hepatic cytosol enzyme activity and total bilirubin concentrations. Serum protein values are primarily normal, but polyclonal hyperglobulinemia can occur. Renal parameters are unaffected. Although various electrolyte abnormalities were reported, no consistent pattern was found.¹³⁰

77.5.3 Microscopic Identification

The definitive diagnosis of babesiosis depends on demonstration of organisms within infected erythrocytes, amplification of babesial DNA extracted from infected blood or tissue, or positive serology results. *B. canis* are large, piriform-shape organisms and usually exist singly or in pairs (see Fig. 77-1, A), whereas smaller single intracellular organisms are likely to be *B. gibsoni* (see Fig. 77-1, B). Parasitemia is often low, especially in *B. canis*-infected dogs, making thorough examination of thin blood smears necessary. With *B. canis* infections, blood collected from the peripheral capillary beds of the ear tip or nail bed may yield higher numbers of parasitized cells.⁶¹ Erythrocytes adjacent to the buffy coat of centrifuged specimens are also more likely to be infected because the organism favors reticulocytes that have higher levels of nucleic acids, amino acids, and adenosine triphosphate (ATP) and lower levels of glutathione.^{169,170} Occasionally, phagocytized organisms and erythrocyte fragments are seen in neutrophils. Although the organisms within erythrocytes may be numerous in some acutely infected animals, they are rarely evident in chronically infected or asymptomatic carriers. Evaluation of stained slides can be tedious and requires a significant time commitment on the part of the laboratory technician. Flow cytometric techniques correlate closely with conventional light microscopic techniques for identification of *Babesia*-parasitized erythrocytes and degree of reticulocytosis.^{9b,41,148} In addition, the methods of concentrating and staining of buffy coat improve the sensitivity of parasite detection.¹⁰⁰ Electron microscopy can also be used by research laboratories to better characterize the parasite.¹²²

77.5.4 Serologic Testing

Because of the difficulties in detecting *Babesia* parasites, especially in chronic carriers, immunodiagnosics may be used to screen for infected hosts. Serodiagnostics have proved reliable as a method of indirect parasite detection in either patent or occult infections that have been present long enough for an immune response to be generated.^{123,158} For canine babesiosis, the indirect fluorescent antibody (FA) test is probably the most specific and most commonly used test for detection of babesial antibody.¹²³ Although laboratory methods differ, generally titers to *B. canis* that are greater than or equal to 1:80 on a single sample are sufficient for diagnosis.

A cut-off titer of 1:320 or greater has been established for incriminating *B. gibsoni* infection.¹⁶⁸ A titer level of 1:1280 or greater has been considered as the cut-off to increase certainty for incrimination of infection in some serologic studies.¹⁶⁸ Titers to multiple species must be measured if serology is performed in geographic areas where more than one type of *Babesia* infection exist. Cross-reactivity between *B. canis* and *B. gibsoni* make parasite identification or PCR necessary to differentiate between the two species. However, very young dogs or

731

732

Infectious Diseases of the Dog and Cat, 3rd Edition

dogs tested early in the disease course may be serologically negative, making it necessary to evaluate convalescing serum in some cases.¹⁵ Antibodies were not detected in 36% of dogs with *B. canis* parasitemia in one study.¹⁵ Enzyme-linked immunosorbent assay (ELISA) and dot-ELISA techniques for antibody detection have been developed. ELISA results are much more sensitive and less specific than those from indirect FA. ELISA testing is used more for seroepidemiologic studies than clinical diagnosis.^{15,123,156a} Using some tests based on whole-cell antigens, dogs infected with *B. gibsoni* may have false-positive serologic test results for *Toxoplasma gondii* and *Neospora caninum* as well as for *B. canis*, especially at lower serum titers¹⁶⁸ Recombinant-produced P50 protein ELISA testing has been more specific for *B. gibsoni* infection than immunoblotting and indirect FA testing.^{42,156a}

77.5.5 Nucleic Acid Detection

Because organisms vary or are infrequent in blood smears, genetic methods are the most sensitive and specific means of detecting infection. Genus-specific screening for *Babesia* can be performed by PCR of DNA extracted from blood samples.^{7,44} Species identification can then be accomplished by comparing small subunit (SSU) ribosomal RNA (rRNA) gene sequences found with known sequences of *B. gibsoni* and *B. canis*.^{37a,58b,115a,76,135} Use of a seminested PCR allows for detection and differentiation of *B. gibsoni* and *B. canis* DNA in blood.¹¹ PCR has been used to identify a third *Babesia* species endemic to the western portion of the United States,^{76,93} a new strain from a dog in North Carolina,^{14a} and another species from northwestern Spain.¹⁷² PCR also detected an organism similar to *Babesia odocoilei* and *Babesia divergens* in ticks from dogs in Japan.⁵⁹

77.6 PATHOLOGIC FINDINGS

Pathologic findings include staining of tissues with hemoglobin or bilirubin, hepatosplenomegaly, lymphadenopathy, and kidneys that are a dark-reddish color.¹⁵⁰ Edema and hemorrhage, which may indicate vascular injury and poor tissue oxygenation in severely affected dogs, are often most severe in the lungs. Large numbers of parasitized erythrocytes may be noted in capillary beds, especially in the brain (Fig. 77-6). Nonparasitized cells often line the endothelial surface with parasitized cells sludged in the lumen. Microthrombi of many tissues may be evident in animals exhibiting signs of DIC. Large numbers of parasitized cells are often evident in the spleen. Impression smears of the spleen may substantiate the diagnosis of babesiosis at necropsy. Organisms can be found in erythrocytes within the microvasculature (Fig. 77-7). Nonspecific findings include erythroid hyperplasia in the bone marrow, extramedullary hematopoiesis of the liver and spleen, mononuclear phagocyte system hyperplasia, and centrilobular necrosis of the liver. Vasculitis has been observed in *B. gibsoni* infections and is associated with hepatitis and lymphadenitis with multifocal deposits of IgM in inflamed arteries and renal glomeruli.¹⁶² In chronic cases of canine babesiosis and cases of feline babesiosis, the only gross finding may be splenomegaly.

Infectious Diseases of the Dog and Cat, 3rd Edition

77.7 THERAPY

77.7.1 Dogs

Dogs generally show clinical improvement within 24 hours of treatment with antibabesial drugs ([Table 77-3](#)⁸¹; see the Drug Formulary, [Appendix 8](#), for additional information). Few drugs have been shown to eliminate the parasites, and most dogs surviving the acute hemolytic crisis develop premunity in which a delicate balance exists between their immune response and the persistent parasite. Unfortunately, two of the most effective of the babesiacidal drugs for *B. canis* infection, diminazene aceturate and phenamidine isethionate, are not approved for use in the United States. Diminazene aceturate is the most commonly used drug worldwide.⁸⁰ It is an aromatic diamidine derivative in the same class of drugs as phenamidine isethionate and pentamidine isethionate. Diminazene aceturate is effective when given intramuscularly (IM), although clearance of infection is inconsistent even at higher doses. *B. gibsoni* infections are less responsive to diminazene than *B. canis* infections. Dogs are more susceptible to the toxic effects of the drug than other species. Side effects include pain and swelling at the injection site, GI irritation, and neurologic manifestations.

a For specific information on each drug, see Drug Formulary, [Appendix 8](#).

b Dose per administration at specified interval.

c Drugs not approved for use in the United States. Available in other countries as oxopirvedine (trade name Merial, Lyon, France), where it is combined with antihistamine, oxomemazine.

d For *B. canis*, this dose is sufficient; for *B. gibsoni*, repeat dose in 24 hours. These total dosages of 7 mg/kg or higher are associated with an increased risk of neurotoxicity.

e Orphan drugs.

f Anecdotal evidence for effectiveness against *B. canis*.

g Only shown to reduce or prevent parasitemia in dogs that were infected during treatment.

h Effective against *B. microti* in people and hamsters. Also effective against *B. gibsoni* in dogs when both azithromycin and atovaquone are used in combination.¹⁴

Infectious Diseases of the Dog and Cat, 3rd Edition

Phenamidine isethionate is available in many countries as a licensed drug for treatment of canine babesiosis. Pentamidine isethionate (trade name Pentam 300; Abbott Labs, Abbott Park, Ill.) has been approved for use in the United States by the Food and Drug Administration as an orphan drug for treatment of *Pneumocystis* pneumonia in people. The drug has been effective against *B. canis* and *B. gibsoni*.⁸¹ The drug has not been as extensively studied as the other diaminidines. Side effects include injection site pain, hypotension, tachycardia, and vomiting.

A carbanilide member of the diaminidine family, imidocarb dipropionate, is an effective drug against *B. canis*.^{6,81} It is available in the United States (see Drug Formulary, [Appendix 8](#)). It is less effective against *B. gibsoni*. At the suggested dose (see [Table 77-3](#)), imidocarb eliminates the *Babesia* infection and eliminates the infectivity of ticks engorging on treated animals for up to 4 weeks after treatment. A single dose of 7.5 mg/kg or a single dose of 6 mg/kg the day following a dose of diminazene at 3.5 mg/kg has also been shown to clear infections.¹¹⁷ 733
734 A dose of 7 mg/kg imidocarb given on days 15 and 27 following experimental *B. canis* infection cleared infection but inhibited the protective response associated with gradual recovery, making the animals more susceptible to reinfection parasitemia than untreated control dogs.¹⁸ Because PCR was not performed and antibody titers persisted, immune stimulation caused by premunition caused by subclinical persistence of the parasite is possible. Imidocarb is also effective against *E. canis* and is therefore the drug of choice in dual infections.⁶ It has protective prophylactic activity up to 6 weeks after a single injection.¹⁵⁵ Side effects are uncommon and thought to be related to an anticholinesterase effect of the drug. They include transient salivation, lacrimation, vomiting, diarrhea, muscle tremor, restlessness, tachycardia, and dyspnea.¹ An overdose of 10 times the proper amount resulted in hepatic necrosis and death in one dog.⁷⁷

Atovaquone is an antiprotozoal drug approved for the treatment of *Pneumocystis carinii* pneumonia in human patients with the human immunodeficiency virus (HIV). The mechanism of action is not completely understood, but the site of action appears to be inhibition of electron transport at the cytochrome bc 1 complex (Complex III) in *Plasmodium* species. Atovaquone and azithromycin are effective against *B. microti* in hamster models^{57,159} and *B. gibsoni* in vitro and in vivo in dogs.^{98b} The combination has proved effective in treating *B. gibsoni* in a pilot study involving a small number of dogs with naturally acquired infection.^{14a} Atovaquone (13.3 mg/kg given orally every 8 hours) and azithromycin (10 mg/kg given orally once daily) were given for 10 days. The treatment appeared to sterilize *B. gibsoni* infections or reduce the parasitemia below detectable limits. Although additional studies on more strains are needed, this may be the treatment of choice for *B. gibsoni* infections in dogs. Atovaquone is difficult to obtain in some countries, and the expense can be much greater than that of other treatments. Recrudescence of infection was observed greater than 30 days following atovaquone monotherapy for *B. gibsoni* infection in dogs.^{98a} Increased resistance to the drug was found by in vitro testing. For this reason, it should always be used in combination with other drugs.

Quinuronium sulfate has been effective in treating dogs with *B. canis* infection.⁷⁸ Dogs showed clinical improvements within 24 to 48 hours of treatment.

Trypan blue (1% solution) is effective in treating dogs with mild to moderate signs of infection with *B. canis* (see [Table 77-3](#)).^{67,133} It has also been recommended for patients with severe infections because it lacks the anticholinergic properties of imidocarb and the CNS toxicity of the other diaminidines.⁸¹ Trypan blue does not clear infections and results in bluish discoloration of tissues and plasma.

Infectious Diseases of the Dog and Cat, 3rd Edition

Aggressive supportive care and clindamycin (25 mg/kg given orally every 12 hours for 7 to 21 days) has been recommended if the specific antibabesial drugs are not available. Clindamycin is the treatment of choice for *B. microti* in people, and numerous anecdotal reports describe success in treating canine babesiosis at 25 to 50 mg/kg/day. However, many infected dogs recover completely without specific babesiacidal therapy if adequate supportive measures are taken, making interpretation of uncontrolled treatment observations difficult. Clindamycin proved effective in managing the acute complications of *B. gibsoni* infections in experimentally infected dogs but did not clear the organisms.¹⁶⁴ Clindamycin at 25 mg/kg given orally every 12 hours for 7 to 21 days after infection resolved anemia and other clinical findings. However, no significant differences were found between treated and untreated dogs in parasitemia levels or antibabesial IgG titers. Nevertheless, morphologic changes in circulating parasites showed degenerative changes. Levels of parasitemia fluctuated in subsequent monitoring in both groups; however, treated dogs had stronger humoral and cell-mediated immune responses against the parasite. Clindamycin was also ineffective compared with oxytetracycline or diminazene for treating experimental *B. canis* infection in mice.⁸

Doxycycline has been effective in preventing or reducing parasitemia in dogs that were being treated at the time of infection.¹⁵⁵

77.7.2 Cats

Treatment of feline babesiosis has not been as critically evaluated as its canine counterpart.⁸¹ Most babesiacidal drugs appear to be ineffective. Primaquine phosphate, an antimalarial compound, administered orally or as an IM injection, is effective and currently the drug of choice (see [Table 77-3](#)). However, the effective dose, 0.5 mg/kg, is very close to the lethal dose of 1 mg/kg. In experimental studies, rifampicin and trimethoprim-sulfadiazine were not as effective as primaquine.¹¹⁸ Danofloxacin, enrofloxacin, and buparvaquone had no anti-*B. felis* activity.

77.7.3 Blood Transfusions

Blood transfusions are usually indicated in severe, uncomplicated cases and complicated cases involving a life-threatening anemia. The decision to transfuse is based on clinical signs, history, and hematologic test results. Clinical signs that would indicate the need for transfusion are tachycardia, tachypnea, water-hammer pulse, weakness, and collapse. The acuteness of onset and the degree of red cell regeneration should also be taken into consideration. The hematocrit is the most commonly used indicator of anemia, but red cell count and hemoglobin can also be used. No HCT has been established at which a transfusion should be given, because it must be evaluated in conjunction with the clinical signs and history. Generally a transfusion is considered when the HCT is 15% or lower and is always indicated when the HCT is 10% or lower. The degree of parasitemia is not an important deciding factor because it often bears little relation to the degree of anemia. Packed red cells are the component of choice for babesiosis. The administration of the plasma component of whole blood is unnecessary in the majority of dogs with babesiosis and can place the patient at risk of volume overload. If rehydration is required, crystalloid replacement solutions are preferable. Fresh whole blood improves oxygen status and acid-base balance in *B. canis*-infected dogs, as well as replaces subfunctional hemoglobin with functional hemoglobin.

Infectious Diseases of the Dog and Cat, 3rd Edition

77.7.4 Supportive Care

Ongoing supportive therapy should be based on a thorough patient assessment and ongoing monitoring, appropriate laboratory testing, and accepted therapeutic principles for the complications that may be present.

Whether glucocorticoids are indicated is controversial. The immune system is implicated in many of the clinical manifestations of canine babesiosis, especially the hemolytic anemia. In one study, 20% of dogs with *B. canis* infection had hemolytic anemias that were not responsive to antibabesial therapy alone.⁶³ Treatment with immunosuppressive doses of glucocorticoids is sometimes necessary. However, long-term use is probably not indicated, and in most dogs the glucocorticoid dosage can be tapered over 2 to 3 weeks. This therapy may predispose the animals to other infections and has the potential to induce babesial relapse.⁹⁷ The monocyte-macrophage system is important in controlling *Babesia* parasitemia. Reduction in this system's function often results in more severe parasitemia shortly after glucocorticoids are initiated.

734

77.8 PREVENTION

735

77.8.1 General Guidelines

The difficulty in obtaining specific therapeutic compounds for treatment of *Babesia* makes prevention of paramount importance. Preventive measures alone may be sufficient to control *B. canis* outbreaks in kennels in the southeastern United States. The primary means of prevention is control of the vector tick.¹³⁴ Frequent inspection of the skin and hair coat for ticks is important because it takes a minimum of 2 to 3 days of feeding for transmission of the parasite to occur. New animals should be serologically tested, treated, and quarantined before being introduced into a colony. Flea and tick collars, although not very effective for flea control, are reasonably effective for tick control when used with inspection, topical ascaricide application, and environmental control. Fipronil (trade names TopSpot, Frontline; Merial, Iselin, N.J.) appears to be effective as a topical product for tick control.

Premunition (subclinical infection) is important in controlling clinical signs of disease in areas where more virulent strains of *Babesia* are endemic.¹¹⁷ In these areas, completely clearing infections may not be desirable. The role premunition plays in immunity in areas where less virulent strains are endemic is not known.

Duration of protective immunity against *B. canis* babesiosis is limited. Antibody titers gradually decline between 3 and 5 months after infection.^{149,154} Dogs are protected against homologous infection within 5 to 8 months after infection.¹⁵⁶ Cross-protection between strains does not occur, and seropositivity is no guarantee of protection against heterologous challenge.

A vaccine produced from cell-culture–derived exoantigens of *B. canis* is available in Europe.¹⁰⁶ An efficacy of 70% to 100% has been reported, with the disease occasionally seen in the vaccinates generally being mild.¹⁰⁵ Other field studies have been less impressive. Vaccination does not prevent infection but appears to block initiation of many of the pathologic processes involved in disease pathogenesis (see Fig. 77-3).^{125,126} Vaccines may limit the parasitemia, reduction in HCT, and development of splenomegaly.¹²⁵ Differences in strain antigenicity substantially limit the usefulness of the commercial vaccine in other areas. However, heterologous

Infectious Diseases of the Dog and Cat, 3rd Edition

protection was achieved using soluble parasite antigens from the European *B. canis vogeli* isolate and South African *B. canis rossi* isolate.¹²⁹

Babesia organisms can be transmitted by transfusion, making control in a blood donor colony especially important.^{38,136} All prospective canine blood donors should be serologically tested for babesiosis. Positive animals should be identified and culled from the program because seropositivity overestimates the infection rate but provides a safer zone for eliminating potential carriers. PCR also offers a fairly sensitive way to detect carriers. When PCR is not available, splenectomy has been used to increase the likelihood of finding parasites in animals with occult infection and therefore is indicated. Blood smears should be examined for *Babesia* daily for 2 weeks after splenectomy and then periodically thereafter.

77.8.2 Babesiosis in Greyhounds and American Pit Bull Terriers

Of the 16,000 greyhounds that were adopted through rescue leagues in 1995, 20% to 60% were likely to have positive serotest results for *B. canis*. Much of this screening was done before the availability of PCR, and serologic testing results likely overestimate the true prevalence of infection. This concern about babesiosis developing in adopted greyhounds is common among adopting owners, greyhound rescue organizations, and veterinarians. The question of what to do with these animals is not an easy one to answer. The likelihood of the adopted greyhound developing clinical babesiosis is low, as is the likelihood of the dog serving as an epidemiologic significant source of spread of the disease. However, the risk to other dogs is great if the infected animal is placed in a breeding kennel in which dogs are housed together and tick control is not adequate or if the animal is used as a canine blood donor. A single IM dose of imidocarb dipropionate at 7.5 mg/kg apparently eliminates the *B. canis* carrier status. This approach should be considered in situations in which risk of spread is likely. In other situations, the owner should be made aware of the seropositive status so that should clinical signs consistent with babesiosis arise, the attending veterinarian can be alerted to the possibility of the disease.

The organism affecting American pit bull terriers is *B. gibsoni*. Most reported cases of *B. gibsoni* in the southeastern United States have been associated with American pit bull terriers. It is common for dogs that are not pit bull dogs and are infected with *B. gibsoni* to have recently been in fights with pit bull dogs.^{10,93} It is therefore important to include questions about recent fights in the history when evaluating a dog for hemolytic anemia.

77.9 PUBLIC HEALTH CONSIDERATIONS

Babesiosis is a significant tickborne zoonosis of people found throughout Europe and in the northeast and upper Midwest of the United States, and isolated cases of uncharacterized *Babesia* have been reported in Africa and Mexico.⁷⁴ The majority of infections are mild or asymptomatic; however, some result in severe illness and death. People who have had a splenectomy or are older (older than 55 years) are especially at risk.^{36,120} No *Babesia* organism has been identified that is host specific for people. Sylvan cycles with wild animal reservoirs occur in nature. As for other tickborne zoonoses, people serve as accidental hosts for *Babesia* of animals when they are bitten by infected ticks. *B. microti* is the primary parasite affecting people in the northeast and upper Midwest of the United States (see Table 77-1). The vector tick is *Ixodes scapularis (dammini)*, the vector tick of Lyme borreliosis (see Chapter 45). The hemolytic disease with flulike symptoms is usually mild and self-limiting or easily managed with clindamycin and quinine. As in dogs, complications of the disease occur in people that have had a splenectomy or have other immunosuppressive illnesses.^{48,52,53}

Infectious Diseases of the Dog and Cat, 3rd Edition

A severe form of human babesiosis is caused by *B. divergens* in Europe and *B. equi* in the United States. This form of the disease usually occurs in people who have had a splenectomy and is often fatal. An organism closely related to *B. divergens*—MO1—was isolated from a person in Missouri who had had a splenectomy and had a fatal illness.⁵² Babesiosis was also identified in Italy and Austria with a new strain (EU1) that was more closely related to *B. odocoilei* than *B. divergens*.⁴⁹ In both instances the people had previously had splenectomies and developed characteristic signs of hemolytic anemia. Identical isolates of *Babesia* have been found in *Ixodes ricinus* ticks from Slovenia, indicating a more widespread distribution of this organism in Europe.

A syndrome of severe anemia that has been reported in people who have had a splenectomy occurs in the western United States.^{121,120} Genetic analysis has shown that this northern California and Washington strain (WA1) is more closely related to (but distinct from) the ilerial species and the California strain of piroplasm in dogs than to other *Babesia*.^{74,120} Historic case reports of human babesiosis caused by domestic animal piroplasms such as *Babesia bovis* or *B. canis* have not been well documented.⁵⁴ However, domestic animals are a source of exposure to the ticks, which may harbor other organisms more likely to infect humans.

78 CHAPTER 78 Enteric Protozoal Infections

The enteric protozoa covered in this chapter are limited to four protozoan genera: *Giardia*, and *Trichomonas*, and *Entamoeba* in the phylum Sarcomastigophora and *Balantidium* in the phylum Ciliophora. Salient characteristics of these organisms and the diseases they may cause are presented in [Table 78-1](#). Enteric protozoa of the phylum Apicomplexa are discussed in [Chapters 80](#) (Toxoplasmosis and Neosporidiosis), [81](#) (Enteric Coccidiosis), and [82](#) (Cryptosporidiosis and Cyclosporiasis). Detailed coverage of laboratory methods for diagnosis of enteric protozoan infections is presented in [Chapter 70](#).

78.1 GIARDIASIS

Stephen C. Barr

78.1.1 Etiology and Epidemiology

Giardia duodenalis (syn. *G. intestinalis*, *G. lamblia*), a protozoan parasite found in the intestinal tracts of human beings and most domestic animals throughout the world, has two morphologic forms.¹²⁸ The intestinal lumen dwelling motile form, the trophozoite, is approximately 15 µm long and 8 µm wide. Under light microscopy, the trophozoite is easily identified by its “smiling face” appearance formed by the two nuclei in the anterior third (forming the eyes), the axonemes passing longitudinally between the nuclei (forming the nose), and the median bodies (forming the mouth) situated transversely in the posterior third ([Fig. 78-1](#)). Four pairs of flagella complete the rather comical appearance of this form. The second form, the cyst, is responsible for transmission and environmental survival. It is approximately 12 µm long and 7 µm wide. Because the cyst contains two incompletely separated but formed trophozoites, the axonemes, fragments of the ventral disks, and up to four nuclei can be seen within ([Fig. 78-2](#)). The cyst is susceptible to desiccation under dry, hot conditions but can survive for several months outside the host in wet, cold conditions. Transmission is fecal-oral route by ingestion of feces or fecal-contaminated water, food, or fomites. The life cycle is direct ([Fig. 78-3](#)). After ingestion, cysts (trophozoites are noninfective) excyst in the duodenum on exposure to gastric acids and pancreatic enzymes. The two released trophozoites separate, mature, and attach to the brush border of the villous epithelium ([Fig. 78-4](#)). The distribution of trophozoites within the intestinal tract varies with host and diet. In dogs, the organism seems to prefer the duodenum and jejunum¹³² but has been found from the ileum to the duodenum.³⁴ Circumstantial evidence indicates that trophozoites occupy the upper intestinal tract (duodenum) in infected symptomatic dogs⁷⁶ and the lower tract (jejunum) in infected asymptomatic dogs.^{9,140} In cats, trophozoites have been found throughout the intestinal tract.^{63,76} In dogs, a high carbohydrate diet rather than a high protein diet¹³² may favor trophozoite habitation of the upper tract. In people, *Giardia* is often found in chronic atrophic gastritis (often associated with *Helicobacter pylori* infection or gastric adenocarcinoma) when a decrease in gastric acidity occurs.^{33,110} Trophozoites adhere (using a ventral adhesive disk) to the brush border of the intestinal mucosa and move from one attachment site to another using flagella. Encystation of trophozoites is stimulated by bile salts and fatty acids at slightly alkaline pH⁴⁶; however, the site and mechanism are unknown. Trophozoites may be passed in diarrheic stools, but cysts are more routinely shed. Whereas cysts may survive for days to weeks in cool, moist conditions, trophozoites do not survive long outside the host. On excretion, the relatively resistant, ellipsoidal cysts are immediately infective to another host.

738

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 78-1 Comparison of Some Enteric Protozoa in Dogs and Cats

ORGANISM	STAGE	AVERAGE SIZE (mm)	NATURAL HOSTS	ORGAN PARASITIZED	PATHOGENIC MECHANISMS	CLINICAL SIGNS
<i>Giardia</i> ^a	Tr	15 × 10 × 3 10 × 8	D, C, H, other mammals	Small intestine	Damage to glycocalyx and microvilli on intestinal epithelium; inhibition of some digestive enzymes; host elicits inflammatory response	None to chronic diarrhea, continuous or intermittent, malabsorption
	Cy					
<i>Entamoeba histolytica</i>	Tr	25 (diam.) 12 (diam.)	D, C, H, NHP	Large intestine	Invades colonic wall, producing ulcers; may metastasize to extraintestinal sites	None to diarrhea; dysentery
	Cy					
<i>Balantidium coli</i>	Tr	60 × 35 50 (diam.)	D, P, H, NHP	Large intestine	Invades colonic wall, producing ulcers metastases (rare)	None to diarrhea; dysentery
	Cy					
<i>Pentatrichomonas hominis</i>	Tr	8 × 5, five flagella	D, C, H, other mammals	Large intestine	Probably none; harmless considered commensal but may be opportunistic pathogen	None to diarrhea
<i>Tritrichomonas foetus</i>	Tr	8 × 5, three flagella	D, C, Ca, P	Genitalia (cattle) Intestine, nasal (swine) Large intestine (cat)	Epithelial adherent, elaboration of cytotoxins and enzymes; host elicits inflammatory response	Large bowel diarrhea in feline; infertility and fetal loss in cattle; diarrhea in co-infected pups

Tr, Trophozoite; Cy, cyst; D, dog; C, cat; H, human being; NHP, nonhuman primate; P, pig; Ca, cattle.

^a Some *Giardia* species may be identical.

Fig 78-1 *Giardia* trophozoite in a fecal smear stained to enhance the characteristic organelles (iron hematoxylin, $\times 2000$).

Fig 78-2 *Giardia* cysts concentrated from the feces of a cat by the zinc sulfate centrifugal flotation technique. Cyst wall, nuclei, axonemes, and median bodies are apparent in several of the cysts (iodine, $\times 1100$).

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 78-3 Diagram of *Giardia* life cycle, indicating organelles of cyst and trophozoite visible by light microscopy. After the cyst (1) is ingested by the host, excystation (2) occurs in the small intestine. Trophozoites (3 through 5) attach to the mucosa or swim freely in the lumen where they divide asexually. Following encystment, cysts are excreted (6) in the feces, completing the cycle. Excreted trophozoites (7) do not survive. Key to structural features: *a*, cyst wall; *b*, nuclei; *c*, axonemes (recurrent flagella); *d*, adhesive disk fragments; *e*, median bodies; *f*, flagella. (From Kirkpatrick CE. 1987. Giardiasis, *Vet Clin North Am*[*Small Anim Pract*] 17:1377–1387. Reprinted with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 78-4 High magnification of trophozoites of *Giardia* sp. attached to intestinal villus of canary (H and E stain, ×1500). (From Gardiner CH et al. 1988. An atlas of protozoan parasites in animal tissues, USDA Agricultural Handbook No. 651, Beltsville, Md.)

The prepatent period of *Giardia* infection ranges from 5 to 12 days (mean, approximately 8 days) in dogs and from 5 to 16 days (mean, approximately 10 days) in cats. The onset of disease, when it occurs, may precede cyst shedding by 1 to 2 days.

The prevalence of *Giardia* is approximately 10% in well attended dogs, 36% to 50% in puppies, and up to 100% in breeding kennels.^{76,107a} The prevalence in cats ranges from 1.4% to 11%.^{62,76} In the general population of both species, the overall prevalence averages approximately 2.5%.^{89,99,129} Although the prevalence of giardiasis is high in cats and dogs, obvious clinical disease is rare. Immunodeficient adults, the young, and group housed animals (breeding kennels, catteries, and laboratory animal colonies) have a high prevalence of clinically apparent *Giardia* infection. Glucocorticoid therapy at antiinflammatory dosages (1 mg/kg/day of prednisolone) for 10 days, allowed replication and reshedding of *Giardia*.¹⁴⁰

78.1.2 Pathogenesis

Because virtually no studies of how *Giardia* causes clinical disease in dogs and cats have been submitted, most of the following information is extrapolated from human studies. In people, infection can cause malabsorption of vitamin B₁₂, folate, iron (leading to anemia),⁵⁹ triglycerides, lactose, and, less commonly, sucrose.⁵⁷ Specific histologic changes have not been identified in the small bowel mucosa¹⁰⁰; however, parasite related pathogenic factors have been implicated in abnormally rapid sloughing of intestinal epithelial cells, leading to failure of new epithelial cells arising in the crypts to differentiate fully into columnar cells with microvilli. Blunting of intestinal villi and microvilli results in decreased absorptive surface area.⁵

Infectious Diseases of the Dog and Cat, 3rd Edition

Putative differences in virulence of *Giardia* strains, as well as host genetics and immune status, probably determine the outcome of an infection. Not only do morphologically identical human *Giardia* isolates vary in respect to their surface antigens,⁹⁵ susceptibility to proteases,⁹⁶ and genetic profiles,²² they also vary in their virulence.^{23,24} An intact cellular and humoral⁷¹ immune system is important for overcoming infection and developing protective immunity.⁴⁰ Absence of an Secretory IgA (S-IgA) response to one of *Giardia* heat shock proteins is associated with persistent infection despite an IgG response to this protein and IgA responses to other *Giardia* polypeptides.²⁶ Few studies involve dogs or cats; the prevalence of *Giardia* infection in a colony of IgA deficient beagles was higher than that of normal animals.⁷⁶ Administration of immunosuppressive amounts of glucocorticoids will lead to recrudescence of *Giardia* infections in dogs.¹⁴⁰

78.1.3 Clinical Findings

Most infections in which cysts are passed in the feces are asymptomatic. Acute diarrhea tends to occur in very young puppies and kittens shortly after infection. In older cats and dogs, diarrhea may be acute and short lived, intermittent, or chronic. Despite the high prevalence of *Giardia* in cats, clinical disease is uncommon. In addition to young animals, those that are stressed, immunosuppressed, or housed in groups have the greatest prevalence of clinical disease. In clinically affected animals, feces are often malodorous, pale, and steatorrheic. Affected animals may experience weight loss secondary to diarrhea, but rarely will they become inappetent.⁷⁶ Although *Giardia* cysts and trophozoites can be seen in the stool of dogs with small or large bowel diarrhea with weight loss,³⁷ the organism is unlikely to be the sole cause of the diarrhea. Giardiasis does not in itself produce fever or emesis.

738

739

78.1.4 Diagnosis

78.1.4.1 Fecal Microscopy

Finding cysts or trophozoites in the feces or samples taken from the intestinal tract is the most definitive means of diagnosing giardiasis because clinical signs and laboratory test results (hemogram, serum biochemistry, radiology) are not pathognomonic. The prevalence of *Giardia* is high, even when giardiasis often goes undetected.⁷ Reasons for this occurrence may include failure to consider the organism in the differential diagnosis, failure to recognize the organisms, use of inappropriate methods for fecal analysis, and intermittent excretion of organisms in feces of infected individuals. Most infected animals passing cysts are asymptomatic, while those with diarrhea shed trophozoites.

A fecal smear, especially in symptomatic patients, may reveal trophozoites that are distinctive by their erratic tumbling motion and concave ventral disk. *Giardia* trophozoites can be distinguished from those of *Trichomonas foetus* or *Pentatrichomonas hominis* (see Trichomoniasis later in this chapter). A drop of feces is mixed with a drop of normal saline on a glass slide, a coverslip is applied, and the specimen is examined immediately with 40 × with the condenser in its lowest position. Morphology of the organisms can be better appreciated by adding a drop of Lugol's iodine, which kills the parasite, thereby rendering it immobile, to a drop of feces. Finding organisms in a fecal smear provides a definitive diagnosis of *Giardia* infection, but a negative result does not rule it out.

Infectious Diseases of the Dog and Cat, 3rd Edition

If a direct smear provides a negative result, the zinc sulfate concentration technique (ZSCT) should be performed.^{76,140} This method is also effective in demonstrating nematode eggs in the feces of cats and dogs and is superior to sucrose (of equal density) flotation because it is less likely to distort the organisms. Commercial ZSCT that do not include centrifugation have a markedly reduced specificity than do techniques that include concentration by centrifugation.¹³⁹ Because cats and dogs shed *Giardia* organisms intermittently,^{61,76} and the presence of organisms in feces does not necessarily parallel the severity of clinical signs, at least three fresh fecal samples should be examined over a period of 3 to 5 days to maximize the chance of ruling out infection. Approximately 70% and 93% of *Giardia* positive dogs can be identified with one and two ZSCTs, respectively.^{76,140} For shipping, fecal samples should be refrigerated at 4° C (39° F) to ensure survival for at least 2 days; cysts will not survive in 10% formalin. Slides prepared by the ZSCT should be examined within 10 minutes of preparation because the cysts shrink with time and lose the internal morphologic characteristic appearance that differentiates them from other organisms. Cysts may be distinguished from coccidian oocysts and sporocysts by internal structure and by observing that *Giardia* cysts will take up iodine, whereas coccidia will not. Yeasts also will stain with iodine; however, yeasts are oval, not ellipsoidal, and are approximately one half the size of *Giardia* cysts. Furthermore, close observation of yeast cells may reveal budding. If steatorrhea frustrates attempts at flotation, the formalin-ethyl acetate sedimentation method to concentrate *Giardia* cysts from a fecal specimen is usually successful.

78.1.4.2

Fecal Immunoassays

Commercial enzyme-linked immunosorbent assay (ELISA) kits to detect fecal *Giardia* antigens (see [Appendix 6](#)) have over 97% sensitivity and over 96% specificity in humans.^{114,145} In dogs, the ProSpecT/*Giardia* ELISA kit (Alexon Inc., Mountain View, Calif.) was found to be slightly less sensitive and have a slightly lower relative specificity than did the ZSCT.⁹ The test may be slightly more effective compared with a single ZSCT in diagnosing *Giardia* infections in dogs.¹⁴¹ In another study, the false negative rate was 31.6% compared with ZSCT, but the specificity was high at 95.7%.¹⁰⁸ Frozen fecal samples or samples preserved in formalin fixative can be used. Given that the ELISA kits are technically more difficult to use and more expensive compared with the ZSCT, they do not seem to offer any advantages over performing three ZSCTs for the diagnosis of giardiasis in dogs. The ELISA has not been adequately evaluated in the cat, although it will detect infected fecal samples.

Similar to the ELISA kits, the direct fluorescent antibody (FA) test (using fluorescent labeled monoclonal antibodies to detect *Giardia* cysts in feces) is highly sensitive (100%) and specific (99.8%) in people.¹⁴⁵ One such test (Merifluor Cryptosporidium/*Giardia* Direct Immunofluorescence Assay, Meridian Diagnostics, Cincinnati, Ohio) is more sensitive than the sucrose gradient flotation and ZSCT are at identifying infected feces from cattle and sheep, especially when the cyst concentration in the feces is low.¹³⁷ In cats, the sensitivities and specificities of the fecal antigen and ZSCT were 95% and 100%, and 87.5% and 75%, respectively. One would expect a similar finding for feces from dogs. Furthermore, direct FA and fecal antigen tests are superior to the ZSCT assay for stored samples because cysts become distorted (creating false-negative readings) and yeast grows in stored samples (creating false-positive readings).⁷⁹ Because direct FA requires a fluorescent microscope, it is more likely to be used in diagnostic laboratories. Feces should be collected fresh and preserved as soon as possible in 10% formalin or sodium acetate-acetic acid formalin.

Infectious Diseases of the Dog and Cat, 3rd Edition

78.1.4.3 Duodenal Sampling

Two techniques used to collect a sample from the duodenum for the microscopic examination of trophozoites have reportedly had disparate findings. In one study, examination for trophozoites of duodenal aspirates collected during gastroduodenoscopy or exploratory laparotomy has been shown to be more efficacious than a ZSCT is on a single fecal sample from the same dogs suffering from clinical giardiasis.¹⁰⁹ However, in another study performed in asymptomatic dogs, a single sample was found to be as effective as a duodenal aspirate was for the diagnosis of giardiasis.¹⁴⁰ The disparity between these findings may be explained by the fact that, in subclinically infected dogs, the organism colonizes various levels (not always including the duodenum) anywhere along the small intestine.³⁴ However, even in animals with diarrhea, intestinal aspiration rarely identifies *Giardia* over and above ZSCT.¹⁰³ Duodenal aspiration to specifically rule out *Giardia* infection is clinically impractical but may be performed if the dog was undergoing gastroduodenoscopy for other reasons and had not previously been treated for *Giardia* or had a ZSCT performed.¹⁰³

The second technique used to sample duodenal contents, a commercially available peroral nylon string test (Entero test, HDC Corp., San Jose, Calif.), has been found to be both safe and accurate for the diagnosis of giardiasis in people.¹¹³ The test is not safe or effective in diagnosing infection in asymptomatic dogs,⁹ although it has been effective in detecting trophozoites in two symptomatic dogs. The test has not been evaluated in cats. See [Appendix 6](#) for information on this product.

739

78.1.4.4 Nucleic Acid Detection

G. intestinalis isolates from people and animals are morphologically similar. Nucleic acid sequence analysis indicates genetic diversity among the isolates. They have been grouped into seven genetic lineages, known as assemblages, A through G ([Table 78-2](#)). Two major zoonotic genotypes (A and B) and animal-specific genotypes (assemblages C through G), such as for dogs or cats, have been found. Within the A genogroup, A-I subtypes are closely related animal and human isolates, while A-II contains only human isolates.¹²⁸ Assemblage B consists of genetically diverse groups of genotypes isolated from people and various animals. These two groups contain the isolates of zoonotic concern. Animals also have their own host-specific strains. The dog-specific types, which are more divergent, have been further divided into types C and D. Cat- and livestock-specific isolates are more closely related to the A and B genotypes, suggesting a more recent genetic divergence.^{3,65,127a} This polymerase chain reaction (PCR) can be used to distinguish between strains of zoonotic risk and those specific to pets. In a study of *Giardia* isolates from domestic, farm and wild animals worldwide, genotypes A and B were widespread in nature and found among diverse types of animals.¹³⁴ Whether this finding represents a cause or effect of human infections is uncertain. In addition, one dog was infected with a mouse-type isolate. PCR has also been used to link human and animal infections (see Public Health Considerations later in this chapter). PCR appears to be sensitive in detecting low levels of infection. Microscopy, ELISA, and PCR methods were used on fecal specimens to determine the prevalence of *Giardia* infection in domestic cats, and rates of 5%, 60%, and 80%, respectively, were found.⁸⁷

740

Infectious Diseases of the Dog and Cat, 3rd Edition

78.1.5 Therapy

In the United States, no drug used to treat giardiasis in small animals is officially approved for that purpose. However, a significant number of licensed drugs that have been employed commonly in human patients to treat giardiasis have been used in small animals. Drug resistance can develop in *Giardia* to any of the available regimens with repeated use, and therefore additional measures for control should be employed. Even if chemotherapy is highly effective, control measures must also be used to prevent reinfection. Some of the reportedly effective treatment regimens in dogs and cats are shown in Table 78-3.* Fenbendazole (Panacur granules 22.2%, Hoechst Roussel Agri Vet Co., Somerville, N.J.), at the dose approved in dogs for the control and removal of roundworms, hookworms, and whipworms, and the tapeworm (*Taenia pisiformis*), was effective in removing *Giardia* cysts from feces in 100% of dogs (six of six dogs treated) in a controlled trial¹³ and in 9 of 10 dogs in another study.¹³⁹ No side effects were seen at this dose regimen, nor is fenbendazole (similar to some other benzimidazoles) thought to be teratogenic. It is safe to treat puppies as young as 6 weeks at these doses. Mild diarrhea has been the only side effect noted. These results suggest that fenbendazole alone may be used to treat giardiasis or to rule out (by therapeutic trial) *Giardia* and whipworm infections as a cause of chronic diarrhea in the dog. Fenbendazole has been evaluated in a group of cats concurrently infected with *Giardia* and *Cryptosporidium*. Of eight cats treated with fenbendazole (50 mg/kg, orally, once daily for 5 days), four remained clear of *Giardia* for the study period (23 days). Three other cats transiently stopped shedding cysts for approximately 1 week after stopping treatment but then resumed. One cat showed only a transient reduction in cyst excretion.^{73,74} A combination product, febantel-praziquantel-pyrantel (Drontal Plus, Bayer Co., Shawnee Mission, Kan.), has similar efficacy to fenbendazole in dogs when used at recommended doses for 3 consecutive days.¹⁰ Similar but slightly lower efficacy was demonstrated when the combination was used once at double the dose or when used at the recommended dose for 2 days.⁴⁵ In six cats treated for 5 days, significant decreases in cyst shedding occurred, and the percentage of positive fecal results was reduced compared with untreated control cats.¹¹⁸ Shedding was not reactivated in four of the cats after immunosuppression with glucocorticoids. The active ingredient against *Giardia* in the combination is thought to be febantel, which is converted to fenbendazole and oxfendazole by the liver. In another study, febantel-praziquantel-pyrantel combination was used in association with strict hygiene procedures to excellent effect, underlining the need to use chemotherapy in association with methods to prevent or limit reinfection.¹⁰⁸ Oxfendazole (11.3 mg/kg, orally, every 24 hours for 3 days; Dolthene, Merial Laboratories, Lyon, France), a benzimidazole used in Europe as a common canine anthelmintic, was also 100% effective against *Giardia* in kennel dogs when used in combination with control methods.¹³⁵ Albendazole given to dogs for 2 days was 90% efficacious in clearing *Giardia* cysts from feces¹²; however, a longer regimen (5 days) is needed in cats.¹¹ No side effects were seen in cats at doses provided or in beagles treated at 30-mg/kg body weight orally once a day for 13 weeks.¹²⁶ However, albendazole is potentially toxic, causing myelosuppression in both dogs and cats. In dogs, toxicity appears to be dose dependent, while in cats, the reaction appears to be idiosyncratic.¹²³ Therefore its use in cats is not recommended. Albendazole, but not fenbendazole, is suspected of being teratogenic²⁹ and therefore should not be given to pregnant animals.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 78-2 Genetic Groupings of *Giardia duodenalis* Morphologic Group^{6,127}

ASSEMBLAGE (GENETIC GROUP)	HOST RANGE
A(Polish strains, Group A1, A2)	A1: People, livestock, cats, dogs, beavers, guinea pigs, slow loris
B(Belgian strains, Group 3)	People, slow loris, chinchillas, dogs, beavers, rats, siamang
C (Dogs)	Australian dog strains
D (Dogs)	Dogs
E (Livestock)	Cattle, goats, pig, sheep, alpacas
F (Cat)	Cats
G (Rat)	Rats
(Muskrat)	Musk rats, voles

Metronidazole (a nitroimidazole) has been administered extensively in dogs and cats for the treatment of giardiasis. It has often been less effective than albendazole or fenbendazole is against *Giardia* in vitro and in vivo. The drug is only 67% effective in eliminating *Giardia* from infected dogs and has been associated with the development anorexia, vomiting, and acute neurologic signs, including progression of pronounced generalized ataxia and vertical positional nystagmus. This situation has resulted in euthanasia in some animals.^{35,42} However, metronidazole benzoate was more effective than fenbendazole was in treating *Giardia*

740

when cats were co-infected with *Cryptosporidium*.¹¹⁷ Cats often resent the administration of metronidazole

741

because of the bitter taste of the tablets; however, this is less of a problem with the benzoate formulation¹¹⁷ (see Drug Formulary, [Appendix 8](#)). Drug resistance to metronidazole by various isolates of *Giardia* is a serious concern in people and in some areas; it is not recommended for the treatment of giardiasis.^{39,133} At high doses (see [Table 78-3](#)), quinacrine is 100% effective but is associated with a 50% rate of side effects (lethargy and fevers) toward the end of the therapeutic regimen.⁷⁶ These side effects regress spontaneously within 2 to 3 days after stopping drug administration. Similar to albendazole and metronidazole, quinacrine should not be given to pregnant animals. Quinacrine has not been demonstrated to be effective in cats.

Infectious Diseases of the Dog and Cat, 3rd Edition

Table 78-3 Drug Therapy for Enteric Protozoal Infections^a

DRUG	SPECIES	DOSE ^b	ROUTE	INTERVAL (HOURS)	DURATION (DAYS)	INFECTION
Fenbendazole	D	50 mg/kg	PO	24	3	G
Albendazole	D	25 mg/kg	PO	12	2	G
	C	25 mg/kg	PO	12	5	G
Metronidazole	D	15–30 mg/kg ^c	PO	12–24	5–7	G, T, A, Ba
	C	10–25 mg/kg	PO	12–24	5–7	G, T, A, Ba
Tinidazole	D	44 mg/kg	PO	24	6	G, T?, A?, Ba?
Ronidazole	C	30–50 mg/kg	PO	12	14	T
Iprnidazole	D	126 mg/L ^d	PO	Ad libitum	7	G
Quinacrine	D	9 mg/kg	PO	24	6	G
	D	6.6 mg/kg	PO	12	5	G
Furazolidone	C	4 mg/kg ^e	PO	12	7–10	G
Tetracycline	D	22 mg/kg	PO	8	7–10	Ba
Paromomycin	C	125–160 mg/kg	PO	12	5	T, A
Combination (10:1 ratio) of Febantel plus praziquantel	B	Febantel: 15 mg/kg plus Praziquantel: 1.5 mg/kg	PO	24	5	G

D, Dog; C, cat; B, both dog and cat; G, giardiasis; T, trichomoniasis; A, amebiasis; B a balantidiasis; ?, uncertain efficacy.

- For additional information on each drug, see Drug Formulary, [Appendix 8](#). For coccidial infections, see [Chapter 81](#); for Cryptosporidiosis, [Chapter 82](#).
- Dose per administration at specified interval.
- Neurotoxicity has been noted with higher doses previously recommended; see Nitroimidazoles, [Chapter 77](#). To facilitate the dosage to smaller animals, the 250- or 500-mg tablets may be ground, or smaller tablet size (50 or 100 mg) may be used. This may be placed in a palatable base. For cats, metronidazole benzoate formulations are better tolerated than USP formulations. See Drug Formulary, [Appendix 8](#).
- In drinking water.
- In suspension, 200 mg/day maximum.

Iprnidazole, a feed water additive for the treatment of blackhead in turkeys caused by *Histomonas meleagridis* and *Trichomonas foetus* in cattle, has been provided effectively in drinking water to treat giardiasis in two greyhounds. Unfortunately, the drug has not been more extensively tested. Tinidazole, another nitroimidazole, has an efficacy against giardiasis similar to metronidazole,⁷⁶ but it is unavailable in the United States.

Furazolidone is effective in treating giardiasis in cats, but side effects of diarrhea and vomiting can occur.⁷⁶ Furazolidone has not been well evaluated in dogs. As is the case with many of the other anti *Giardia* compounds, furazolidone is suspected of being teratogenic and should not be used in pregnant queens.⁷⁶ See the Drug Formulary, [Appendix 8](#), for more information on these drugs.

Infectious Diseases of the Dog and Cat, 3rd Edition

78.1.6 Vaccination

Giardia vaccine (GiardiaVax, Fort Dodge Animal Health, Overland Park, Kan.) for cats and dogs composed of chemically inactivated trophozoites became commercially available early in 2000. Pups and kittens (age 7 weeks and naïve to *Giardia* exposure) that received one vaccine and a booster 3 weeks later were immune to a *Giardia* challenge 6 and 12 months later.^{103,106} In other studies using older dogs, vaccination reduced the duration of cyst shedding and the number of cysts shed.¹⁰⁴ Of 817 dogs receiving the vaccine, 97% showed no local or systemic vaccine-associated reactions, and those that did react developed only mild, transient, injection site reactions.¹⁰² The vaccine has been used as an immunotherapeutic agent in dogs. Thirteen dogs that failed to be cured of giardiasis using chemotherapeutic measures showed clinical cures and cessation of fecal cyst shedding between 3 to 10 weeks postvaccination (some dogs required up to three vaccines).¹⁰⁴ However, in other studies, vaccination failed to prevent reinfection.¹⁰⁸ *Giardia* vaccination has not been an effective treatment for asymptomatic canine *Giardia* infections.^{5a} Furthermore, the present author (SBC) has seen numerous asymptotically infected dogs develop clinical symptoms of diarrhea after receiving the vaccine. *Giardia* vaccination at 4, 6, and 10 weeks after cats were experimentally infected failed to clear the infection, suggesting that the vaccine may not be efficacious in cats that already infected.¹²² Although the vaccine might have a place in the treatment of some chronically infected dogs in which chemotherapy and hygiene control methods have failed, its utility appears small for use as a general vaccine for the control of giardiasis in the general population of dogs or cats that are invariably exposed to the organism before vaccination.

78.1.7 Prevention

To date, no drug has been convincingly proven to be 100% effective against *Giardia*. Trials testing the efficacy of drugs against *Giardia* are based on clearing cysts from feces, not removing organisms from the intestinal tract. Thus, because the possibility exists that these compounds do not clear organisms but only inhibit cyst production for a time, whether treated animals may be a source of infection in the future is unknown. Certainly, autoinfection occurs by virtue of viable cysts present in fecal material adherent to the external haircoat or present in a cold, moist environment. Because the prepatent period can be extremely short for *Giardia*, an animal may become reinfected and start excreting cysts again within 5 days after the last treatment. Because of these factors, preventing reinfection of household pets or animals held in uncontrolled environments is virtually impossible. Preliminary trials in kittens, using a killed trophozoite vaccine (Langford/Cyanamid, Guelph, Ontario, Canada) has shown protection against diarrhea, weight loss, and cyst shedding.¹⁰⁵ Lesser numbers or no cysts and reduced cyst viability were found in vaccinates compared with unvaccinated kittens.

In controlled environments (cattery or kennel situation), four main approaches should be employed to control *Giardia*: (1) decontaminating the environment, (2) using drugs to treat animals, (3) cleaning cysts from coats, and (4) preventing reintroduction of infection.⁸

In a cattery or kennel, first, establishing a “clean area” is necessary. In a small facility, all the animals should be moved out of the facility while it is being cleaned. In a large facility, clean areas can be created over time by setting up a few cages or runs on a rotation basis once animals are moved out to a holding facility. Before moving animals to the holding facility, they should be treated (preferably with fenbendazole or febantel-praziquantel-pyrantel combination) and moved to the holding facility on the last day of treatment. Once moved, the cages or runs should be steam or chemically cleaned after all fecal material has been picked up. Quaternary ammonium (QUAT)-containing disinfectants (Roccal, Winthrop Labs, New York, N.Y.; Totil,

Infectious Diseases of the Dog and Cat, 3rd Edition

Calgon Corp., St. Louis, Mo.), when used at the manufacturers' recommended concentrations, are effective in inactivating *Giardia* cysts (1 minute at room temperature).⁷⁶ QUATs lose considerable activity when used in the presence of organic matter. The kennel should be allowed to dry thoroughly after cleaning (cysts are extremely susceptible to drying) and preferably left dry and empty for several days before being repopulated. Before repopulating the clean area, the animals should be bathed to remove all fecal material from their coats with a general pet shampoo and thoroughly rinsed. The animals should be bathed again (especially the perianal area) with a QUAT compound. QUAT compounds can irritate skin and mucous membranes with repeated or prolonged exposure but appear to produce no ill effects when applied for 3 to 5 minutes followed by thorough rinsing. The coat is allowed to dry thoroughly before returning the animal to the clean area. Animals should then be treated again, preferably with a different compound than the one initially used, once back in the clean facility. Theoretically, the only way *Giardia* can be reintroduced into a clean area is by an infected animal or by fomite transmission. New animals introduced into the kennel or cattery should be treated and their coats cleansed as discussed, regardless of whether they are *Giardia* negative on fecal examination. Fomite transmission can be avoided by donning shoe covers before entering the facility or cleaning boots with a QUAT footbath. Fecal samples should be periodically checked using the ZSCT, which should detect whether the process has been effective.

78.1.8 Public Health Considerations

Giardia is the most common intestinal parasite, affecting people worldwide. Many infections are acquired by drinking unfiltered municipal water originating from *Giardia* contaminated streams, rivers, or lakes.⁶⁶ Infants and children in day care facilities appear to have a particularly high risk for infection. Furthermore, giardiasis has been regarded as an emerging disease in developed countries. Approximately 200 million people in Asia, Africa, and Latin America have symptomatic giardiasis.¹³⁶ Contaminated water is an important vehicle for transmission of this infection. Although scant direct evidence links zoonotic infections from dogs and cats, molecular and immunologic analyses of assemblage A group I (A-I) and B *Giardia* isolates from animals, including dogs and cats, and people suggest that they are not highly host specific.^{14,38,58} The A-I and B isolates that parasitize people have been found in cysts from fecal samples of dogs, cats, some farm animals, and wild animals, suggesting that these genotypes are widespread and possibly zoonotic.¹³⁴ Of the human genotypes, only those of the A-I type have been found in cats. Genetic studies of host infections over time suggest that mixed populations of genotypes do not persist, and the better host-adapted strain eventually predominates.¹²⁷ For example, the higher infection rate in Aboriginal dogs in Australia allows the better-adapted dog strain to dominate.¹²⁷ In these communities, both people and dogs are commonly infected. However, almost all the dogs harbor the canine-specific strain.^{64,65} Similarly, in metropolitan Perth, Australia, all but one genotype isolated from cats was a dog strain.⁸⁷ This situation contrasts with some urban areas where the prevalence of infection has been lower, but the infecting strain in dogs is usually a zoonotic one from assemblages A-I or B. In kennels in central Italy, 23% of the isolates from dogs were assemblage A-I with potential zoonotic implications and the remainder was the dog genotype.¹⁷ In genetic studies on a focus of infection in a remote Indian subcontinent community, canine isolates were in the human assemblages A-I and B.^{130,131} An epidemiologic association was made between the prevalence of *Giardia* infection in people and dogs within the same households.

Chlorine disinfection of public drinking water is not completely effective in controlling *Giardia* contamination, and filtration should also be used.^{110a} Organic chlorine compounds such as *N* halamines are stable in water and have shown marked efficacy in inactivating *Giardia* cysts within 2 minutes at 22° C (72° F).

Infectious Diseases of the Dog and Cat, 3rd Edition

78.2 AMEBIASIS

Stephen C. Barr

78.2.1 Etiology and Epidemiology

Entamoeba histolytica is a facultatively parasitic ameba that predominantly infects people and nonhuman primates. Genetic analysis has shown that, within a given geographic region, families of closely associated people harbor unique strains.¹⁴² This finding suggests that household members, including pets, are at risk for exposure. Although the prevalence of amebiasis in the United States has declined considerably over the last several decades, *E. histolytica* remains an important parasite in many tropical areas around the world.

Trophozoites either inhabit the colonic lumen as commensals or invade the colonic wall. Rarely do they disseminate to other organs such as the liver, lungs, brain, perianal skin, and genitalia (Figs. 78-5 and 78-6). Various strains of *E. histolytica* differ in virulence. Cysts, passed in human feces, are the infective stages. Because encystment of trophozoites rarely occurs in dogs and cats, amebiasis is among the unusual diseases that are transmissible from people to pets but seldom vice versa.

Willertia is a genus of free living saprophytic amebas that are closely related to *Naegleria*. The latter species has been identified in human infections in which trophozoites are found in tissues. In contrast to these locally invasive infections, *Acanthamoeba* disseminates to other tissues and encysts (see Chapter 79).

742

743

Fig 78-5 Schematic depiction of *E. histolytica* trophozoite (A) and various stages of cyst development (B through E). Key: c, chromatoid bodies; g, glycogen vacuole; k, karyosome; n, nucleus; r.b.c., red blood cell; end., endoplasm; ect., ectoplasm. (From Brown HW, Neva FA. 1983. Basic clinical parasitology, ed 5, Appleton Century Crofts, Norwalk, Conn., with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 78-6 Numerous *E. histolytica* trophozoites in a section from the wall of a human colon. Each organism contains a single, darkly stained nucleus; in some of the trophozoites, pale vacuoles are apparent (H and E stain, ×540).

78.2.2 Pathogenesis and Pathologic Findings

E. histolytica trophozoites damage the intestine by attaching to and lysing host cells and secreting enzymes that disrupt intercellular connections. The presence of certain bacteria and a host with deficient protein intake contribute to parasite virulence. The host's own cellular immune response to tissue invading amebas can exacerbate the damage. Secretory diarrhea may be induced by serotonin and other factors secreted by the trophozoites.

Mucosal IgA antibodies to the amebic adherence lectin have been shown to provide resistance to enteric infection in people.¹²⁰ However, immunity is transient and reinfections are common. Secretory immunity is also important in preventing dissemination and subsequent development of hepatic abscesses.

Invasive amebiasis results in erosion or ulceration of the colonic mucosa. Microscopic examination of infected colonic tissue may reveal the classic flask shaped ulcer of amebiasis, which is the result of mucosal undermining by trophozoites in the submucosa. Trophozoites may be seen in sections stained with hematoxylin and eosin, iron hematoxylin, or periodic acid-Schiff reaction.

78.2.3 Clinical Findings

E. histolytica infections are usually asymptomatic but can lead to signs of severe ulcerative colitis, including dysentery. Fulminant, untreated amebiasis may prove fatal. Extraintestinal amebiasis, a serious complication, is rare in dogs and unknown in cats. In such cases, signs would be referable to the parasitized tissue (e.g., lung).

Infectious Diseases of the Dog and Cat, 3rd Edition

Vulval swelling and bloody vaginal discharge have been reported in a dog with uterine, cervical, and vaginal invasion with trophozoites.

A gastric infection with *Willertia* was described in a dog with gastric ulceration and adenocarcinoma.¹²¹ The dog had been receiving glucocorticoids for paraparesis and was vomiting and had melena.

78.2.4 Diagnosis and Therapy

Definitive diagnosis of amebiasis in dogs and cats requires finding *E. histolytica* trophozoites in feces or tissues (see [Table 78-1](#)). Trophozoites are difficult to detect in fecal specimens. Direct smears of fresh feces reveal the sluggish, ameboid motility of the trophozoites. In invasive amebiasis, trophozoites may contain erythrocytes. Macrophages in feces may be confused with trophozoites. Methylene blue staining of a wet mount may be helpful in revealing amebas. Trichrome or iron hematoxylin-stained fecal smears are ideal for diagnosis, but these techniques are best left to a reference laboratory (see [Appendix 5](#)). Fecal concentration methods (e.g., flotation, sedimentation) are unsuitable for *E. histolytica* trophozoites. In clinically affected animals, a more reliable means of detecting the trophozoites is the microscopic examination of a sectioned biopsy specimen of colonic mucosa (see [Fig. 78-6](#)). An ELISA based antigen test has been shown to be parasite specific in dogs,⁹⁸ but its clinical application has not been evaluated. For available test kits, see [Appendix 6](#).

743

744

Fig 78-7 Schematic diagram of a *B. coli* trophozoite (**A**) and cyst (**B**). Key: c, cilia; cv., contractile vacuole; cy., cytophyge; f, food vacuole; g, gullet; m, mouth; ma.n, macronucleus; mi.n, micronucleus. (From Brown HW, Neva FA. 1983. Basic clinical parasitology, ed 5, Appleton Century Crofts, Norwalk, Conn., with permission.)

Infectious Diseases of the Dog and Cat, 3rd Edition

Colitis caused by *E. histolytica* rapidly responds to metronidazole at doses recommended for treatment of giardiasis (see [Table 78-3](#)), but dogs can continue to shed organisms.^{5,70} Paromomycin has been used to treat people; however, precautions should be used because of potential nephrotoxicity (see Therapy under Trichomoniasis).

Diagnosis of free living amebiasis is best achieved by tissue biopsy. Trophozoites, rather than cysts, are identified in tissue margins of the ulcer and in the serosal exudate. Immunostaining can be used to determine the species of ameba present.¹¹⁴ For further information on Acanthamebiasis, see [Chapter 79](#).

78.2.5 Public Health Considerations

Although amebiasis is a potentially serious human disease, dogs and cats are not likely significant reservoirs of these parasites for people. Dogs and cats more likely acquire their infections from human feces or from food or water contaminated by human feces. Although amebiasis is not a zoonosis, the finding of *E. histolytica* in a pet should prompt the veterinarian to suggest that the owners seek medical advice. The owners may have infected the pet or been exposed to a common source of *E. histolytica* cysts. With free living amebiasis, people and animals are at risk for exposure to the same environmental sources. Immunocompetency is important in determining whether infection becomes established.

78.3 BALANTIDIASIS

Stephen C. Barr

78.3.1 Etiology and Epidemiology

Balantidium coli is a relatively large (see [Table 78-1](#)), ciliated protozoan ([Figs. 78-7](#) and [78-8](#)) found throughout the world. Although the pig is the most frequently infected animal, dogs and people sometimes become infected with *B. coli*. Infection in the cat has not been reported. In a large survey of 56 mammalian species in Japan, nonhuman primates and artiodactyls were infected, and no rodents or carnivores, including dogs or cats, were infected.⁹⁴ Similar to *E. histolytica*, *B. coli* trophozoites inhabit the colon, either as commensals or invasive parasites, and cysts are passed in the feces. Cysts are infective when ingested by a susceptible host.

Infectious Diseases of the Dog and Cat, 3rd Edition

Fig 78-8 Large intestine of gorilla containing *Balantidium* sp. with large macronucleus and distinct cilia (×1500). (From Gardiner CH et al. 1988. An atlas of protozoan parasites in animal tissues, USDA Agricultural Handbook No. 651, Beltsville, Md.)

78.3.2 Pathogenesis and Pathologic Findings

The question as to why normally commensal *B. coli* trophozoites may become virulent in some instances remains unanswered. Certain colonic bacteria and concurrent whipworm (*Trichuris vulpis*) infections may contribute to *B. coli* invasiveness.

The gross and microscopic features of balantidiasis closely resemble those of amebiasis in the colon. Unlike amebiasis, extraintestinal metastasis of *B. coli* trophozoites is rare. Routinely processed sections of affected colonic tissue will reveal the trophozoites with their characteristic cilia and bean shaped macronucleus (Fig. 78-9).

744

745

78.3.3 Clinical Findings

Balantidiasis is clinically indistinguishable from some other causes of hemorrhagic colitis, including amebiasis and trichuriasis. A history of contact with swine may be present, although pigs are usually asymptomatic.

78.3.4 Diagnosis and Therapy

B. coli cysts and, occasionally, trophozoites may be detected on fecal flotation using the ZSCT. Fresh fecal smears in an isotonic solution are preferred to demonstrate the motile trophozoites. The distinctive macronucleus of both cyst and trophozoite (see Figs. 78-8 and 78-9) is invisible unless stained. A drop of acidic methyl green solution (1 g methyl green, 1 ml glacial acetic acid, 100 ml water) added to the preparation will reveal the macronucleus in most of the organisms after a few minutes of contact.

Infectious Diseases of the Dog and Cat, 3rd Edition

Reports of therapy of canine balantidiasis are few.²⁸ Tetracyclines and phenethylamines have been used. Based on human clinical studies, oral metronidazole should also prove effective in the dog. See [Table 78-3](#) for dosages.

78.3.5 Public Health Considerations

Because *B. coli*-infected dogs may excrete cysts in feces, the potential for transmission from dog to people exists. Compared with swine, because dogs are rarely infected, they cannot be considered significant reservoirs of *B. coli* for people.

78.4 BLASTOCYSTOSIS

Craig E. Greene

78.4.1 Etiology and Epidemiology

Blastocystis hominis, a waterborne commensal, is now a protozoan that inhabits human and animal intestinal tracts. Its pathogenicity in causing gastrointestinal illness in people is controversial. *Blastocystis* organisms isolated from various animals are similar to *B. hominis*.^{4,36} Genetic analysis has separated the isolated strains into seven groups.¹ Using this phylogenetic data, animal isolates have been given unique species names, and others can be found in people, indicating zoonotic potential. The organisms found in dogs and cats were slightly smaller and had few vacuoles compared with *B. hominis* by light and by transmission electron microscopy.³⁶ In Brisbane, Australia, prevalence rates of organisms in the stools from domestic dogs and cats predominantly in animal shelters were over 0.8% and 67.3%, respectively. In the presumed life cycle, resistant fecal cysts are ingested and develop into vacuolar forms that replicate by binary fission.^{125a} Some of these forms mature into cysts that are shed in the feces. Prevalence of infection is highest in areas of poor sanitation.

Fig 78-9 *B. coli* trophozoites in a section from the wall of a human colon. Note the prominent parasite macronuclei and the surrounding inflammatory response (H and E stain, ×250).

Infectious Diseases of the Dog and Cat, 3rd Edition

78.4.2 Clinical Findings

The organism has been found in a high percentage of clinically healthy animals; its pathogenic role in dogs or cats is uncertain.

78.4.3 Diagnosis

Blastocystis in canine feces ranged from 3 to 10 μm and irregular in shape. In unstained wet mounts, organisms had a thin outer rim of cytoplasm, containing barely discernable organelles, surrounded by a variably shaped central vacuole (Fig. 78-10, A and B).³⁶ In feline feces, the organisms were between 2 to 10 μm and had a similar vacuolar appearance. *Blastocystis* spp. have been cultured from canine feces in prerduced inspissated egg stunt medium covered with Forcke's solution.³⁶ Internal structures of the organism can be visualized by electron microscopy (Fig. 78-11, A and B). They possess a nucleus, mitochondria, Golgi complex, and endoplasmic reticulum. As is the case with light microscopy, a thin rim of cytoplasm surrounds a large central vacuole.

78.4.4 Therapy

Although the pathogenicity of *B. hominis* in people is controversial, people are often treated when it is the only apparent cause of diarrhea. Metronidazole for 10 days has been used to treat affected people.⁹⁷ Clinical improvement and a reduction in the number of organisms in the stool were observed. Relapses were observed after 6 months in some of the treated patients, presumably as a result of reinfection. Nitazoxanide has also been used to treat people with *Blastocystis* infection, as well as a significant number of other protozoal infections.^{27,32}

78.4.5 Public Health Considerations

Though *Blastocystis* may be a commensal, it is associated with signs of diarrhea and cutaneous rashes in immunocompromised people. Although morphologic features suggest similarities among human and animal *Blastocystis* organisms, insufficient evidence exists to support or refute this possibility.

78.5 TRICHOMONIASIS

Jody L. Gookin

78.5.1 Etiology and Epidemiology

Trichomonads are spindle to pear-shaped, highly motile flagellates similar in size to *Giardia*. They exist only as trophozoites (no cyst stage), divide by binary fission, and are transmitted directly via the fecal-oral route. Trophozoites bear characteristic numbers of anteriorly directed flagella and a single, posteriorly directed flagellum that arises at the anterior end and courses along the body attached to the undulating membrane, a characteristic feature of trichomonads. A rigid, rod-shaped organelle, the axostyle, runs through the trophozoite and protrudes from the posterior end (Fig. 78-12).

Infectious Diseases of the Dog and Cat, 3rd Edition

Pentatrichomonas hominis has five anterior flagella, is considered to be nonpathogenic, and inhabits the large intestine of a large number of mammalian hosts, including cats, dogs, and people. Natural and experimental infections with *P. hominis* in dogs and cats were described in the early 1900s; however, clinical signs were either absent or largely attributable to coexisting intestinal infection.¹⁹ DNA of *P. hominis* was isolated from the feces of a litter of pups with diarrhea containing trichomonads and *Isospora canis* oocyst.^{48a} Only one published report of feline diarrhea associated with intestinal trichomoniasis has been submitted over the 60-year period before 1996,⁷² perhaps because *P. hominis* was presumed to be opportunistic. Since 1996, however, numerous reports of diarrhea associated with trichomoniasis in cats have been published.* Detailed morphologic and genetic analyses of isolates obtained from affected cats have identified the trichomonads as *Tritrichomonas foetus*,^{48,54,84} which had not been previously described in the cat.

Fig 78-11 Transmission electron microscopy of *Blastocystis* sp. in culture from canine fecal material. **A**, Low magnification showing general cell morphology. Variability is noted in the central vacuolar (cv) contents. One cell shows projections of the cytoplasm (as indicated by arrowheads) into the central vacuole. Numerous bacteria (b) are present in the culture. **B**, High magnification showing details of the nuclear region. A crescentic band of electron opaque material (indicated by asterisk) is present in the nucleus. Mitochondria (m) and a lipid inclusion (l) are seen in the cytoplasm. A surface coat (sc) surrounds the cell. Small granules are present in the central vacuole (cv). (Courtesy Deborah Stenzel, Queensland University of Technology, Brisbane, Australia.)

T. foetus is recognized as an important venereal pathogen of naturally bred cattle in which the organism is transmitted from the prepuce of the bull to the vagina and uterus where infection leads to infertility and abortion.¹⁸ The organism has also been described as an inhabitant of the porcine gastrointestinal and nasal mucosa where its pathogenicity is uncertain.^{43,124} *T. foetus* and *T. suis* are considered to be strains of the same species based on morphology, ultrastructural analysis, random amplified polymorphic DNA analysis, enzyme homogeneity, and rRNA gene sequence identity.¹²⁵ Cross-transmission studies between cattle and swine with *T. foetus* or *T. suis* have revealed little host specificity.⁴³ The natural history of *T. foetus* in the feline host and any relationship to bovine or swine trichomoniasis needs further evaluation.

Fig 78-12 Drawing of *P. hominis* trophozoite indicating some of the characteristic organelles. Key: *a*, anterior flagella; *b*, posterior flagellum; *c*, nucleus; *d*, undulating membrane; *e*, axostyle. (Modified from Wenrich SH. 1947, The species of *Trichomonas* in man, *J Parasitol* 33:177–188, with permission.)

The prevalence of *T. foetus* infection was 31% among 117 cats from 89 cattery owners attending an international cat show.⁵⁴ Evidence of the organism was found in feces from 18 cat breeds from 17 states and Germany based on direct microscopic examination, protozoal culture, or PCR of feces. Catteries in which *T. foetus* was identified had larger numbers of cats with diarrhea and lower numbers of square feet of facility per cat, suggesting that crowding may be a significant risk factor for infection. Proximity of a cattery to agricultural species (pigs, cattle, horses), feeding of raw meat, type of water source, outdoor contact, or history of travel were not identified as significant risk factors for *T. foetus* infection. Co-infection by *T. foetus* and *Giardia* was common. *T. foetus* was not demonstrated by either direct microscopic examination or protozoal culture of feces from 100 feral cats or 20 healthy indoor cats from geographic regions comparable to those of naturally infected cats.⁴⁹ Thus *T. foetus* does not appear to be a component of the normal feline intestinal flora. DNA of *T. foetus* was identified in the diarrheic feces of pups having profuse watery diarrhea and co-existing *Giardia* infection.^{48a}

78.5.2 Pathogenesis

Multiple organism, host, and environmental factors are likely involved in the pathogenesis of diarrhea in cats with *T. foetus* infection. Pathogenic factors associated with trichomonads include interaction with endogenous bacterial flora, adherence to host epithelium, and elaboration of cytotoxins and enzymes.⁴¹ Infection of specific-pathogen-free cats with axenically cultured *T. foetus* results in chronic colonization of the terminal ileum, cecum and colon, and large bowel diarrhea akin to that observed in naturally infected cats.⁵² In naturally infected cats, *T. foetus* antigen can be demonstrated within the superficial mucus and in contact with the surface epithelium of the cecum and colon. Antigen uptake by surface epithelial cells is also evident. Whether long-term infection of cats with *T. foetus* is a predisposing factor for development of inflammatory bowel disease is unknown. The predominance of young cats from dense housing conditions may reflect an increased opportunity for exposure or enhanced susceptibility to infection because of environmental stress or immunologic immaturity.

78.5.3 Clinical Findings

The widely accepted view is that *P. hominis* does not cause disease in dogs and cats, although the possibility exists that it is an opportunistic pathogen. Though a large number of trophozoites have been described in diarrheic feces from dogs, an unambiguous, causal relationship remains to be established.

Cats with diarrhea and *T. foetus* infection are generally young but have ranged in age from 3 months to 13 years. In one study, approximately 75% of cats were younger than age 1 year at the time of diagnosis.⁴⁹ Infections are seen in both nonpurebred (sheltered) and purebred (cattery) cats.

Feline *T. foetus* infection is characterized by a waxing and waning large bowel diarrhea that occasionally contains fresh blood and mucus. Diarrhea is semiformal to cow-pie in consistency and malodorous. In very young cats and with poor housing conditions, the anus may appear edematous, erythematous, and painful; involuntary dribbling of feces or rectal prolapse may be seen. In general, cats otherwise maintain good health and body condition. A consistent feature of *T. foetus* diarrhea is improved fecal consistency and disappearance of trichomonads during administration of antimicrobial drugs with return of diarrhea containing trichomonads shortly after drugs are discontinued.⁴⁹ Misdiagnosis of *Giardia* is common in cats having *T. foetus* infection. Cats diagnosed with *Giardia* based on direct fecal smear examination and that fail to respond to appropriate antimicrobial therapy should be closely reevaluated for the possibility that the observed trophozoites were *T. foetus*.

78.5.4 Diagnosis

78.5.4.1 Direct Fecal Smear Examination

Diagnosis is made by observation of trophozoites in feces diluted with saline solution and examined under a coverslip using a light microscope equipped with a 20 × or 40 × objective (Fig. 78-13).⁴⁹ Lowering the microscope condenser to increase contrast may enhance visualization. Trichomonad trophozoites must be distinguished from those of *Giardia*. *Giardia* trophozoites have a concave ventral disk and motility reminiscent of a “falling leaf.” In contrast, trichomonads are spindle shaped, possess a single nucleus with no

Infectious Diseases of the Dog and Cat, 3rd Edition

concave disk, have an undulating membrane that courses the entire length of the body, and have a jerky, rolling forward motility (Fig. 78-14). *T. foetus* can be difficult to distinguish with any reliability from nonpathogenic intestinal trichomonads such as *P. hominis* based on light microscopic appearance because the two organisms differ in appearance only by the number of anterior flagella.
